The 1000 genomes project

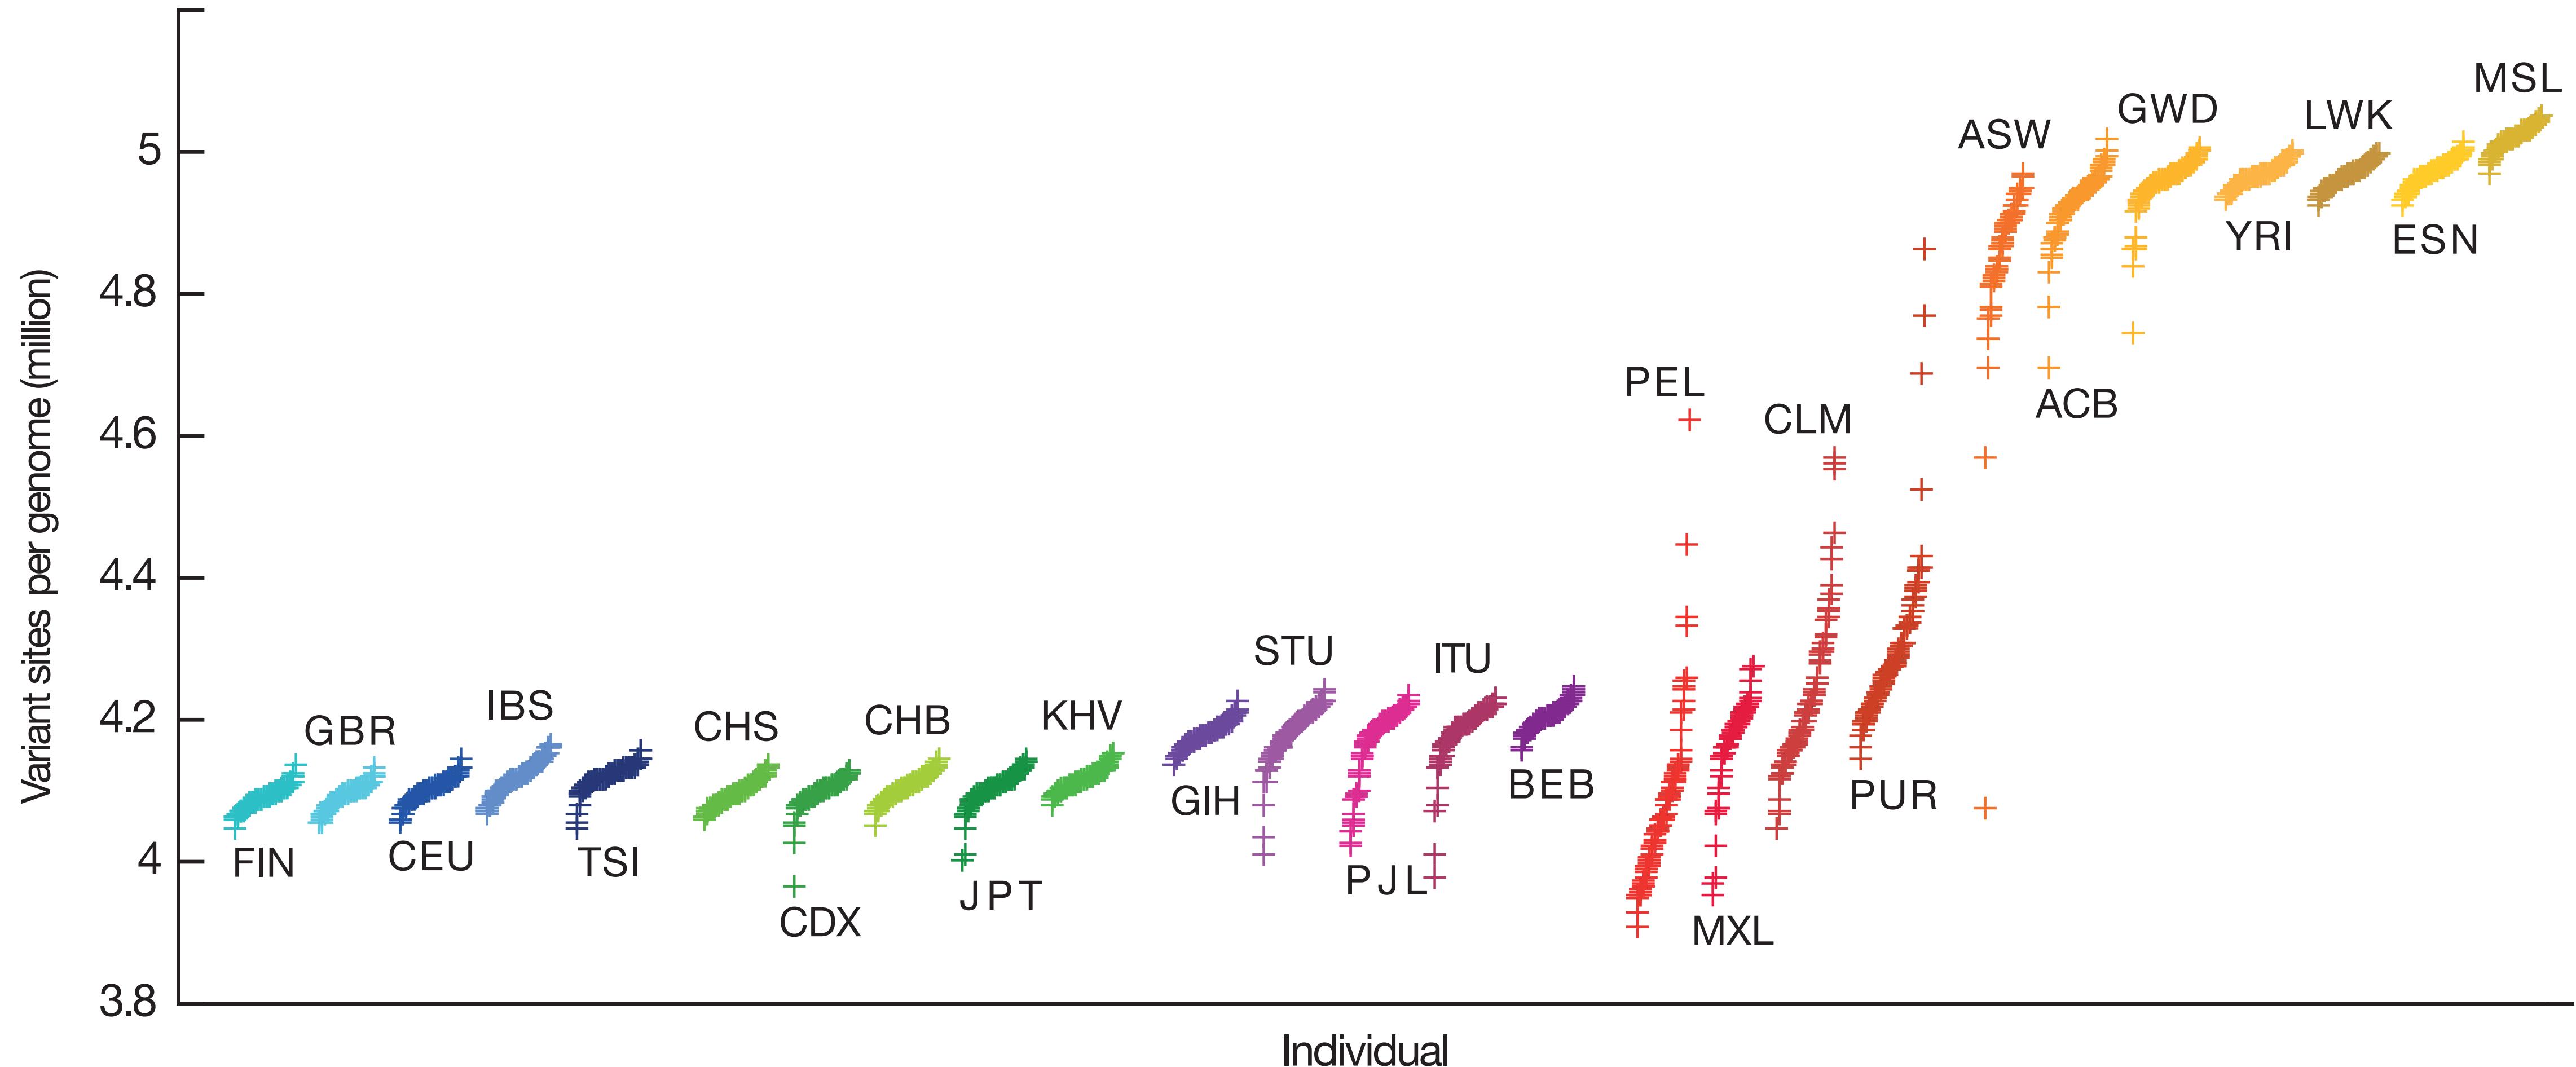

Whole Genome Sequencing & Variant calling
across 1000 individuals in many different groups

Genetic variation across human population

A typical genome

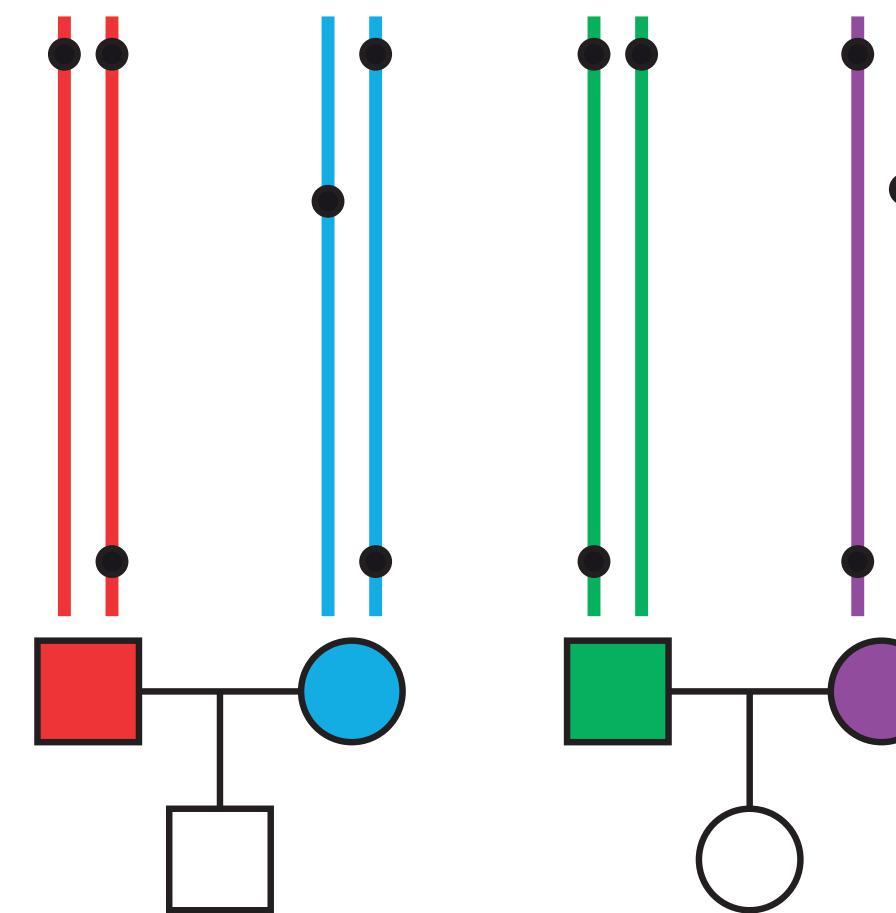

We find that a typical genome differs from the reference human genome at 4.1 million to 5.0 million sites (Fig. 1b and Table 1). Although >99.9% of variants consist of SNPs and short indels, structural variants affect more bases: the typical genome contains an estimated 2,100 to 2,500 structural variants (\sim 1,000 large deletions, \sim 160 copy-number variants, \sim 915 Alu insertions, \sim 128 L1 insertions, \sim 51 SVA insertions, \sim 4 NUMTs, and \sim 10 inversions), affecting \sim 20 million bases of sequence.

A typical genome differs from the reference at 4.1 to 5 million sites

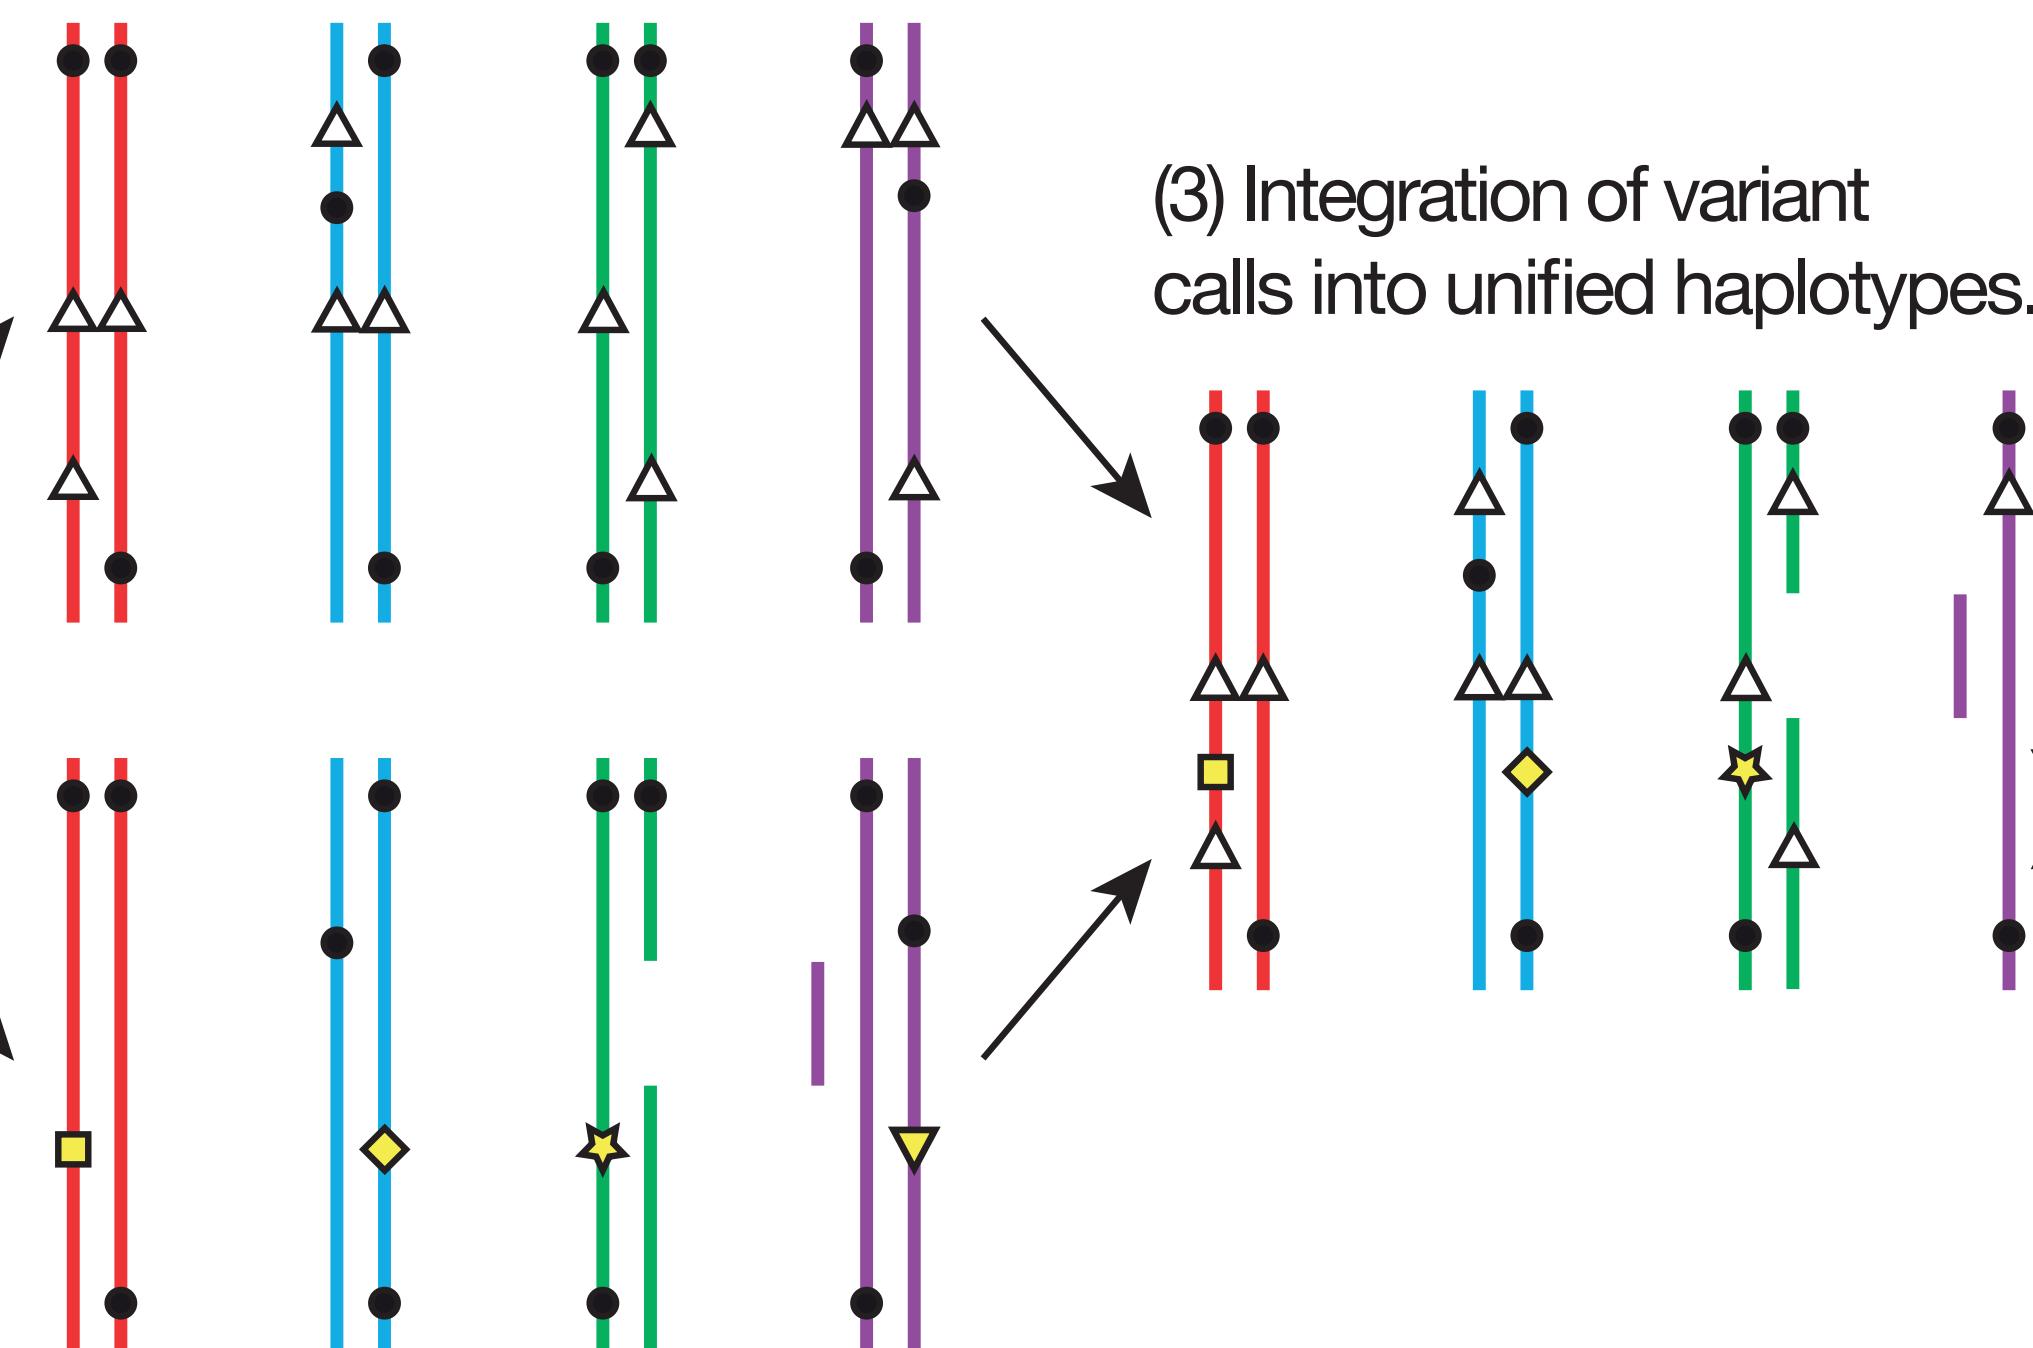

Haplotype

(1) Construction of haplotype scaffold from SNP microarray genotypes, using trio data where available.

(2a) Joint genotyping and statistical phasing of biallelic variants from sequence data onto haplotype scaffold.

(2b) Independent genotyping and phasing of multi-allelic and complex variants onto haplotype scaffold.

Allele

A different form of a gene
[from a Greek word,
ἀλληλο, ἀλλος, "allos",
other]

A different version of a gene

A different version of the
same variant

Mostly used for a gene

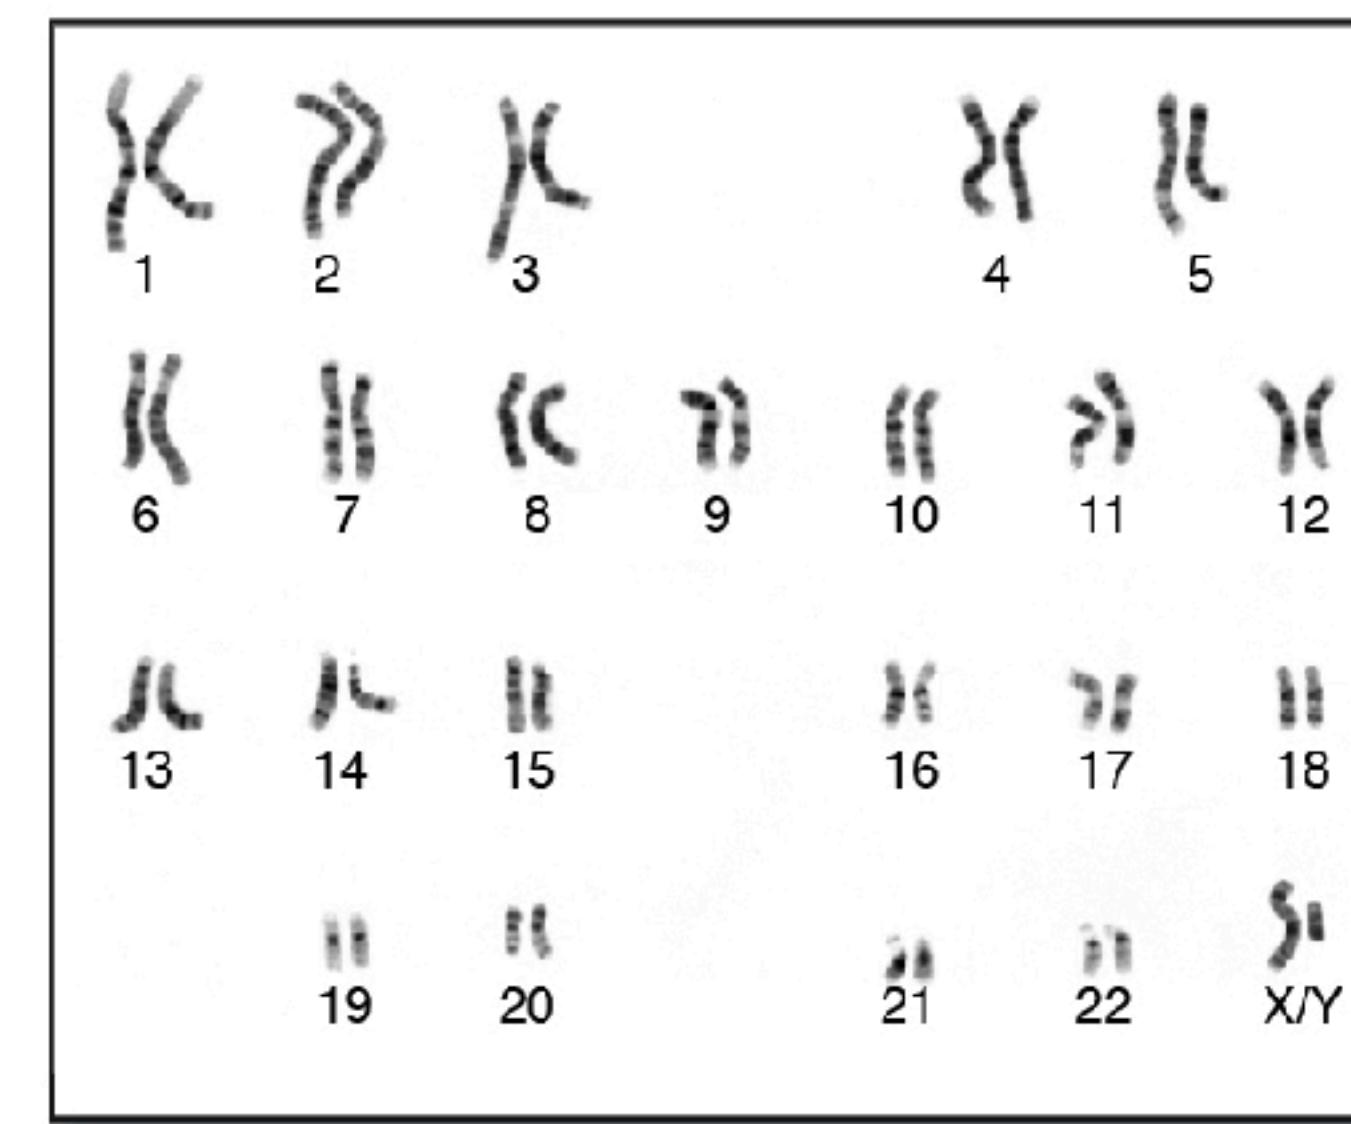

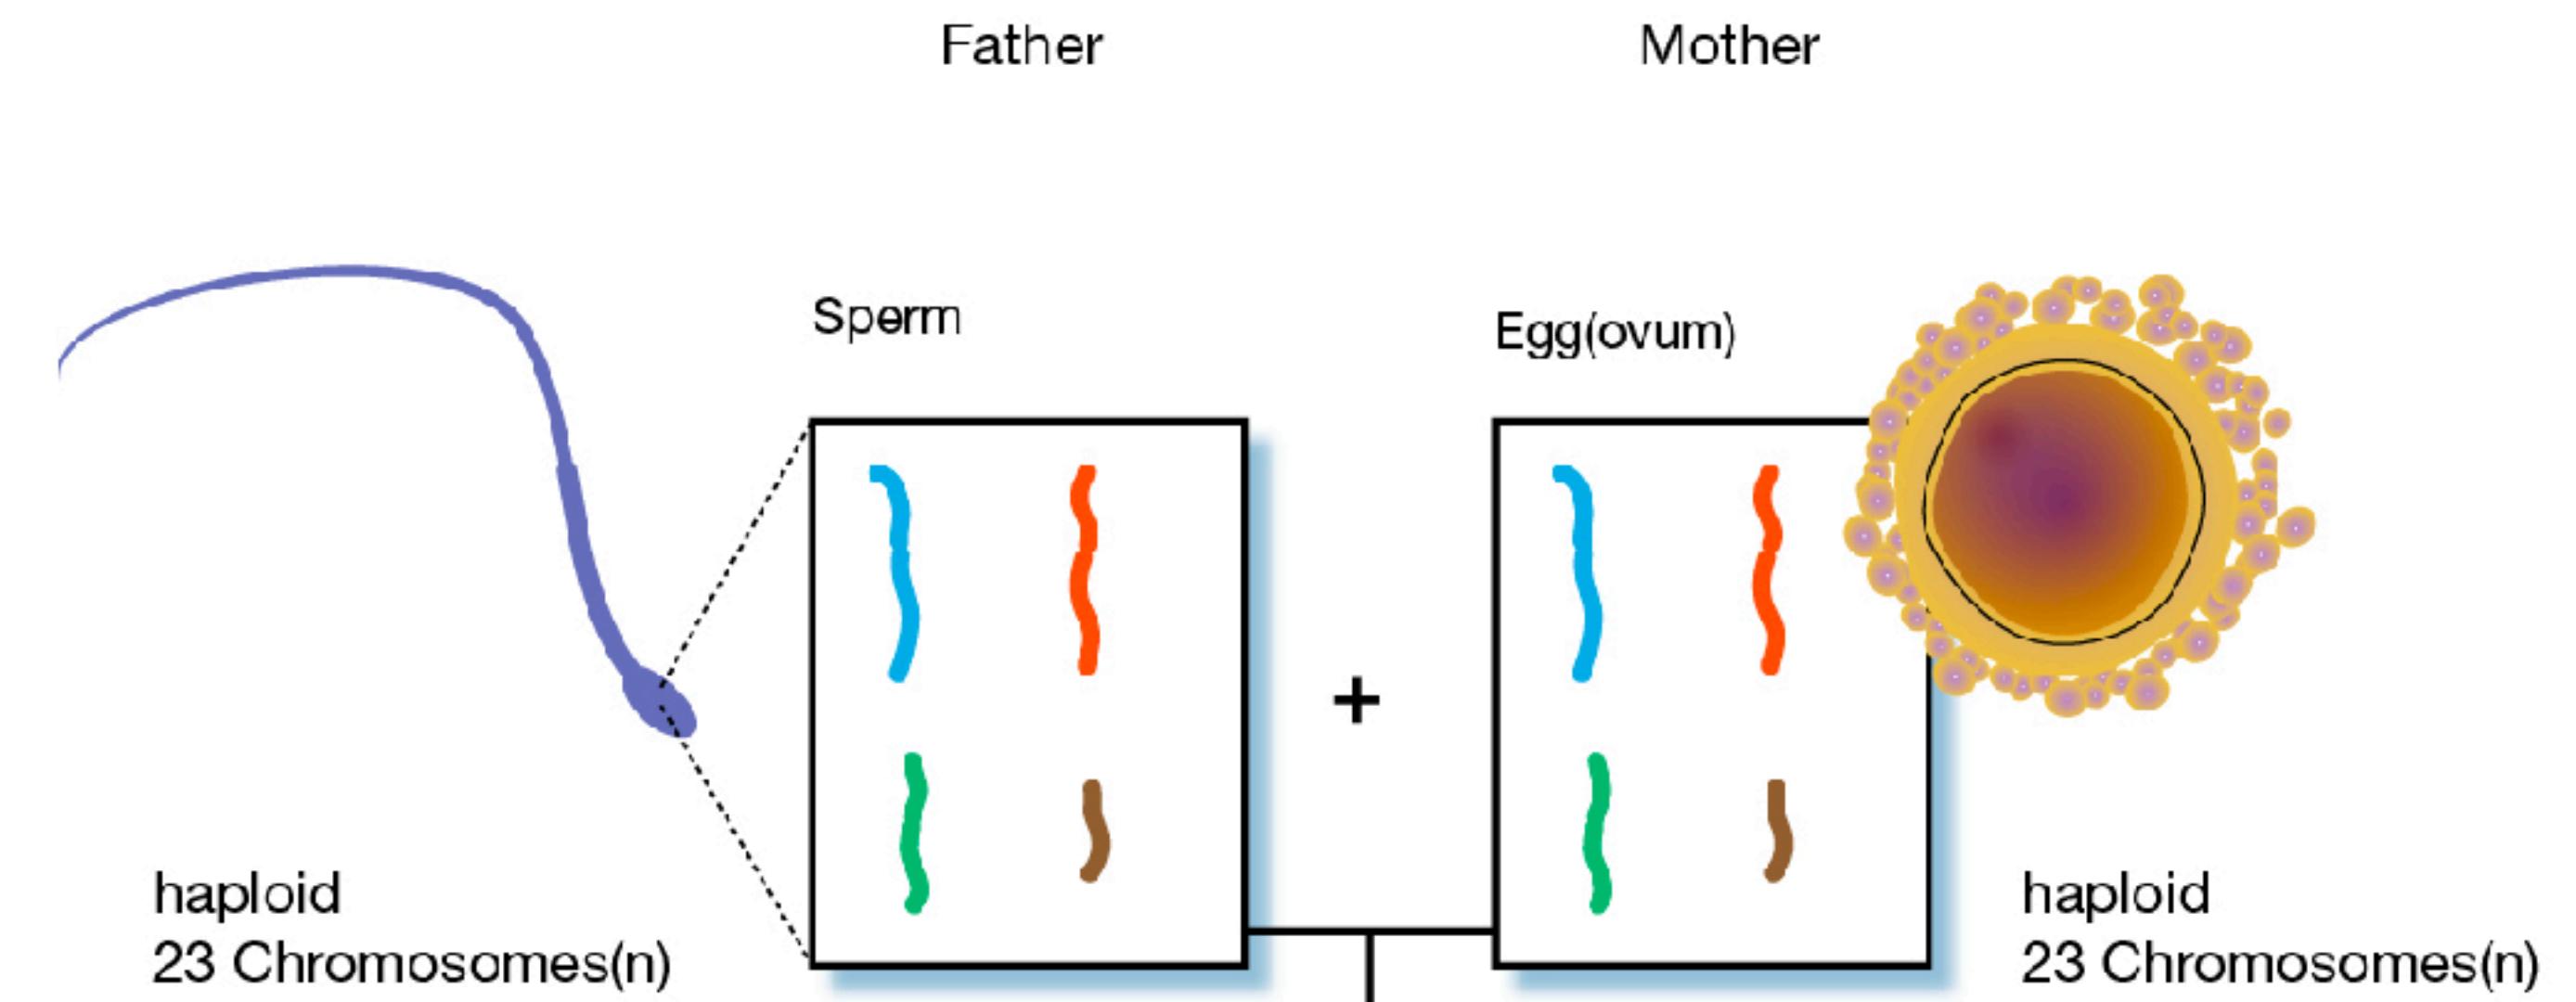

Variant

A specific region of the
genome differs between
two genomes.

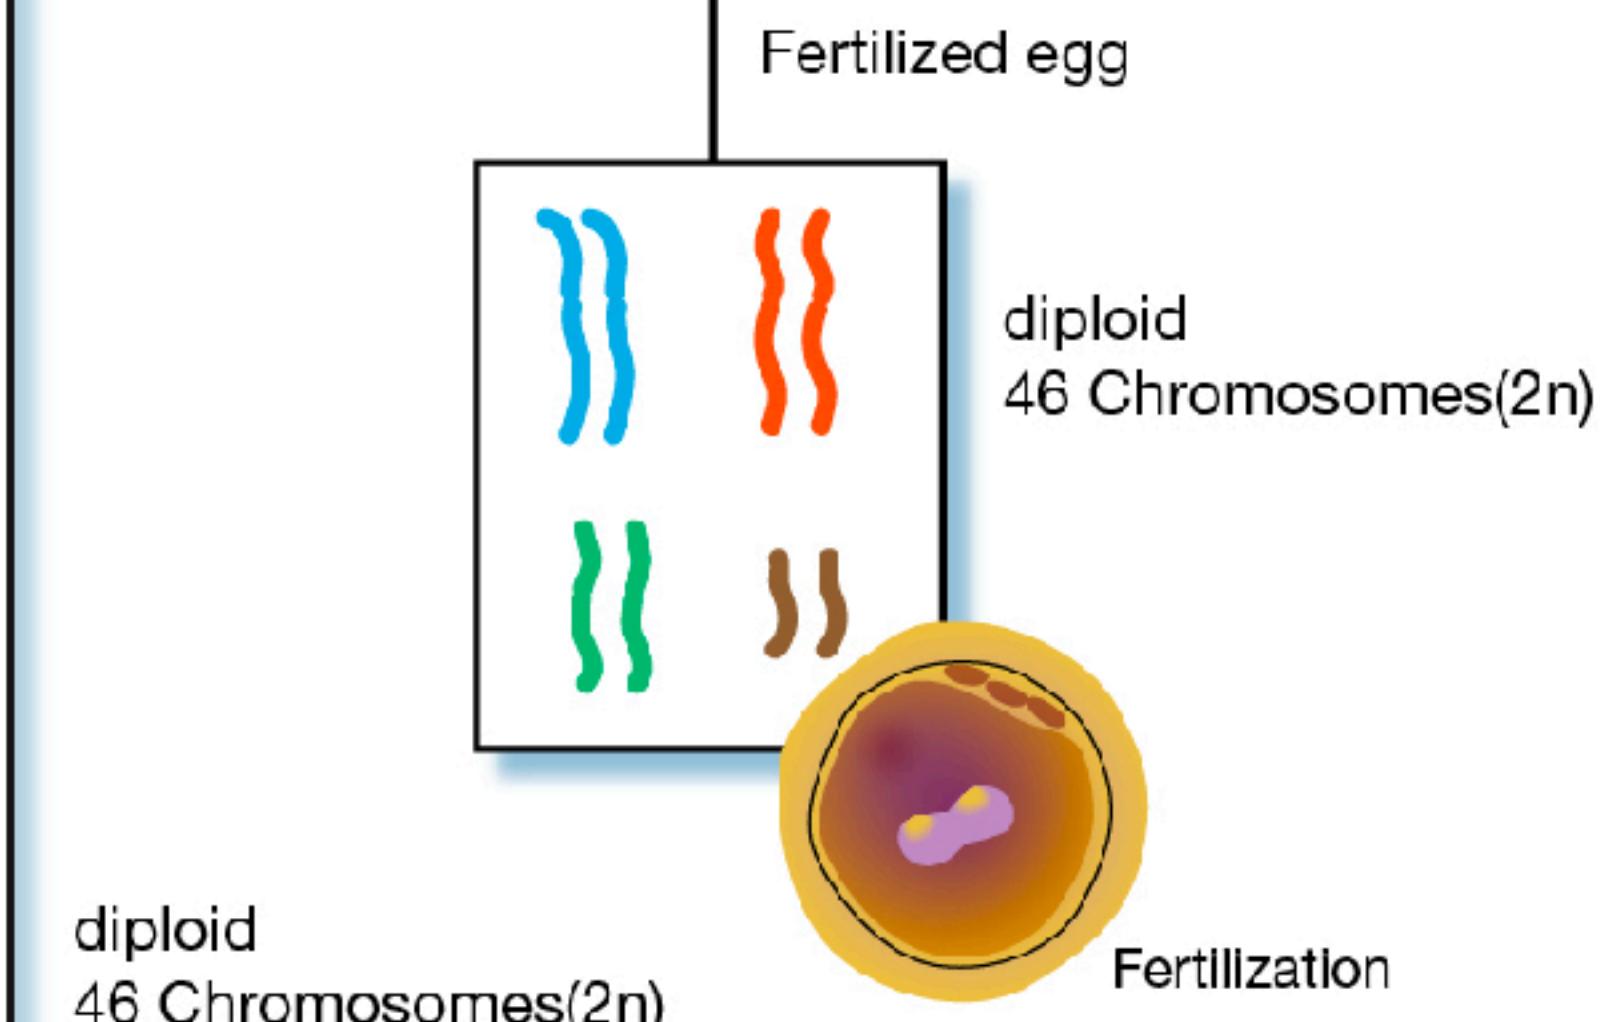

Across two or more
genomes, there could have
genetic variants due to a
mutational process

Ploidy (diploid)

One copy from
maternal genome
another copy from
paternal genome

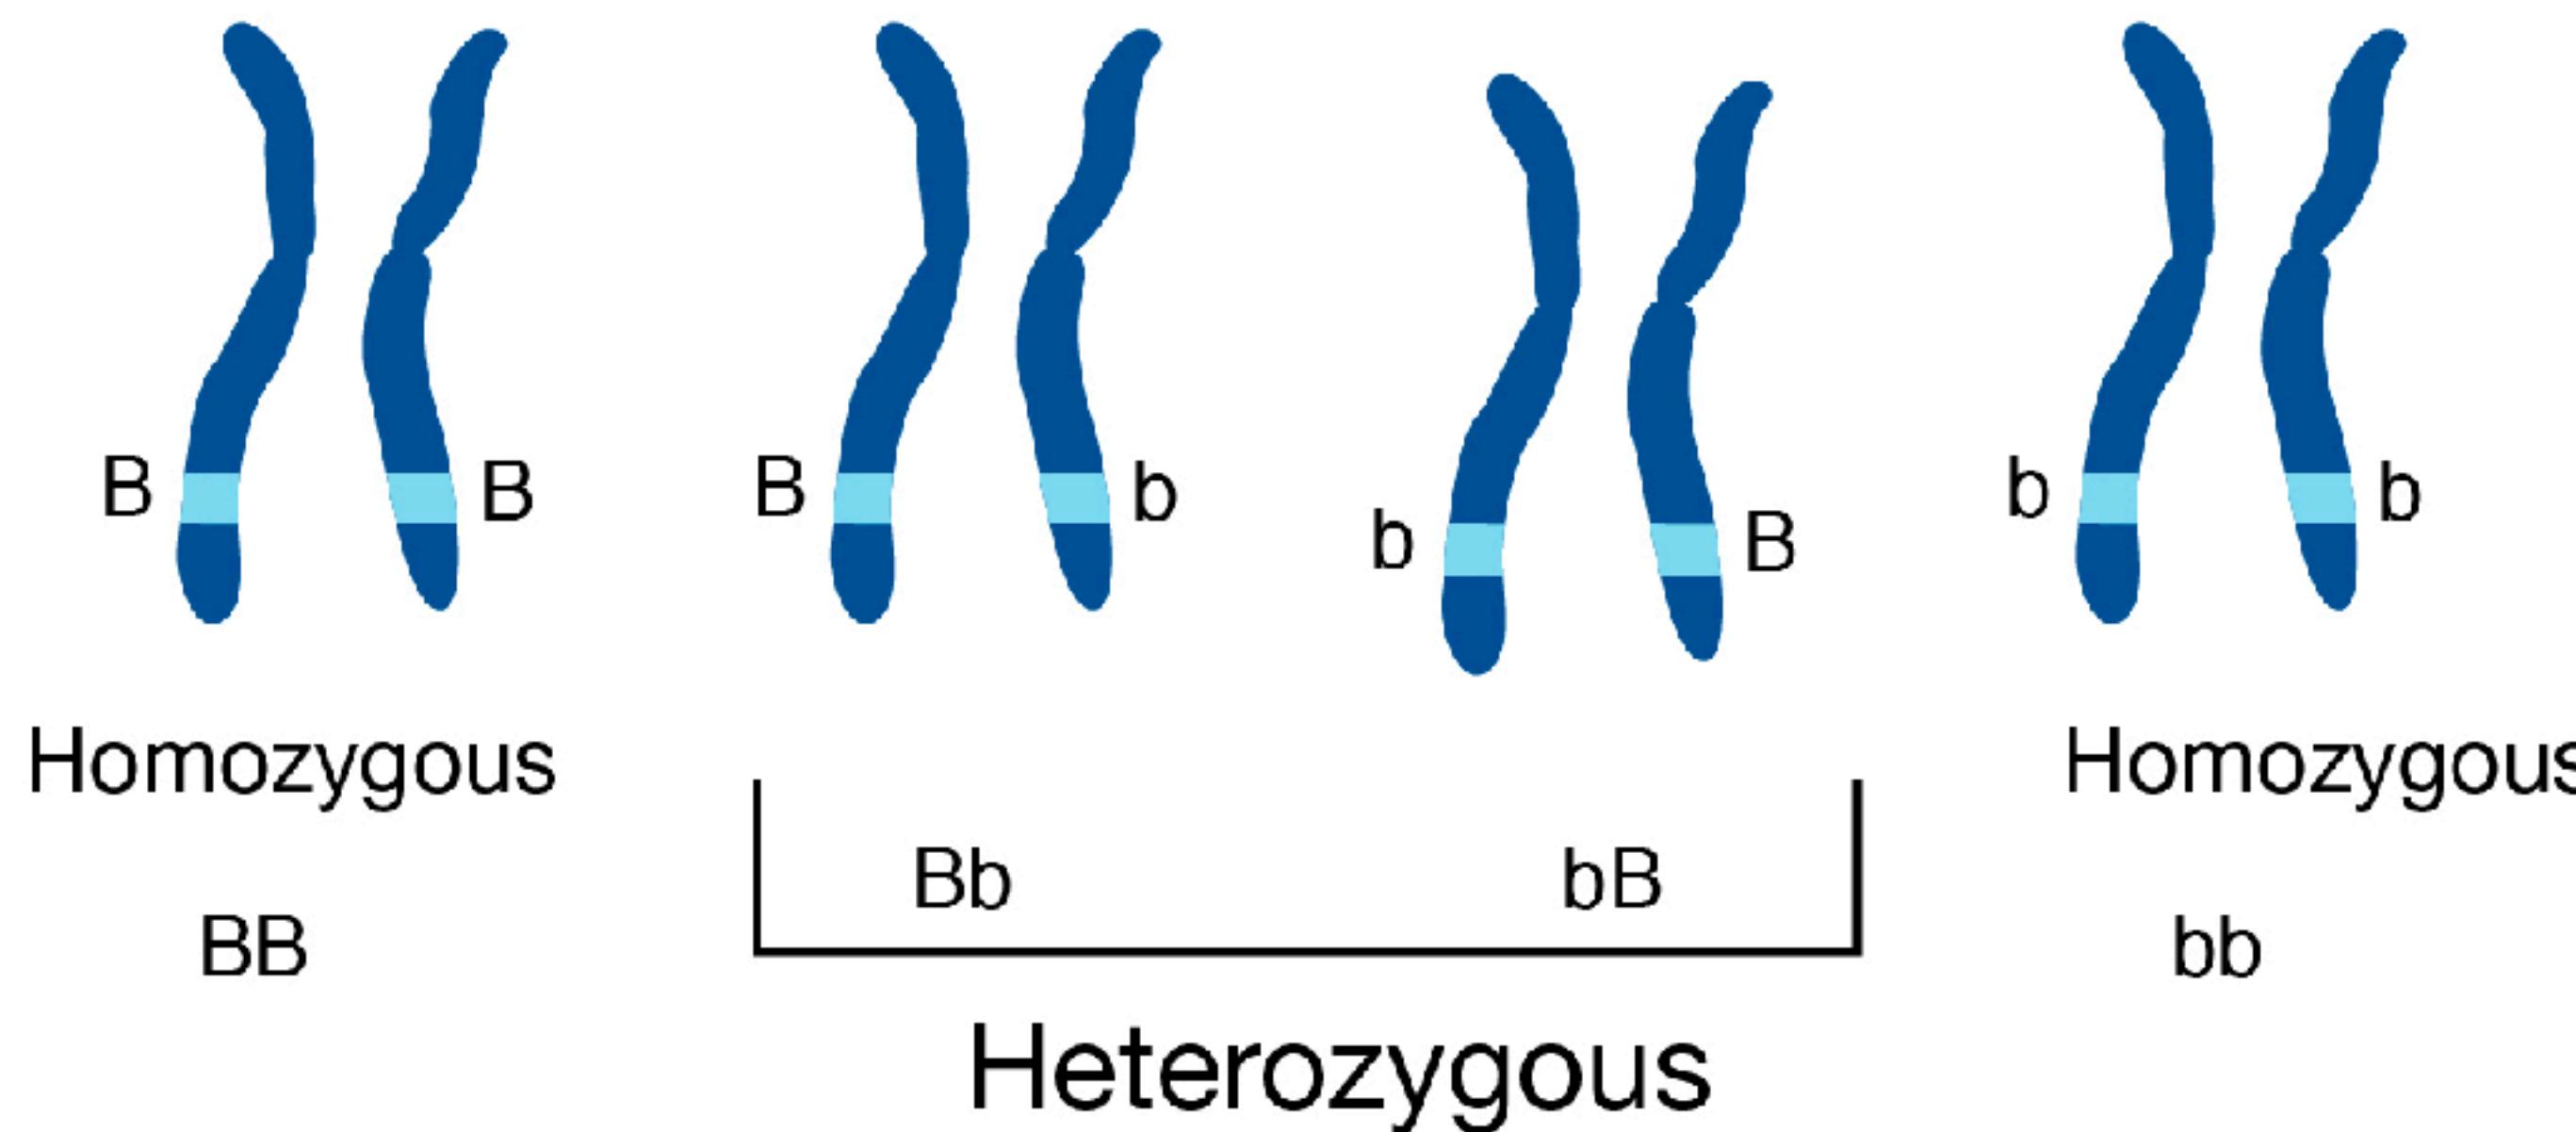

When do we have
polyploidy or
aneuploidy?

Biallelic vs. triallelic vs. multiallelic

"Bi"-allelic: two different forms exist for this heritable unit (most of the human variants)

"Tri"-allelic: three different forms exist (much rare than biallelic variants)

For biallelic variant:

- reference allele
- alternative allele

Many types of genetic variants

ACTGACG--TGCATCATGCATGC

Indel

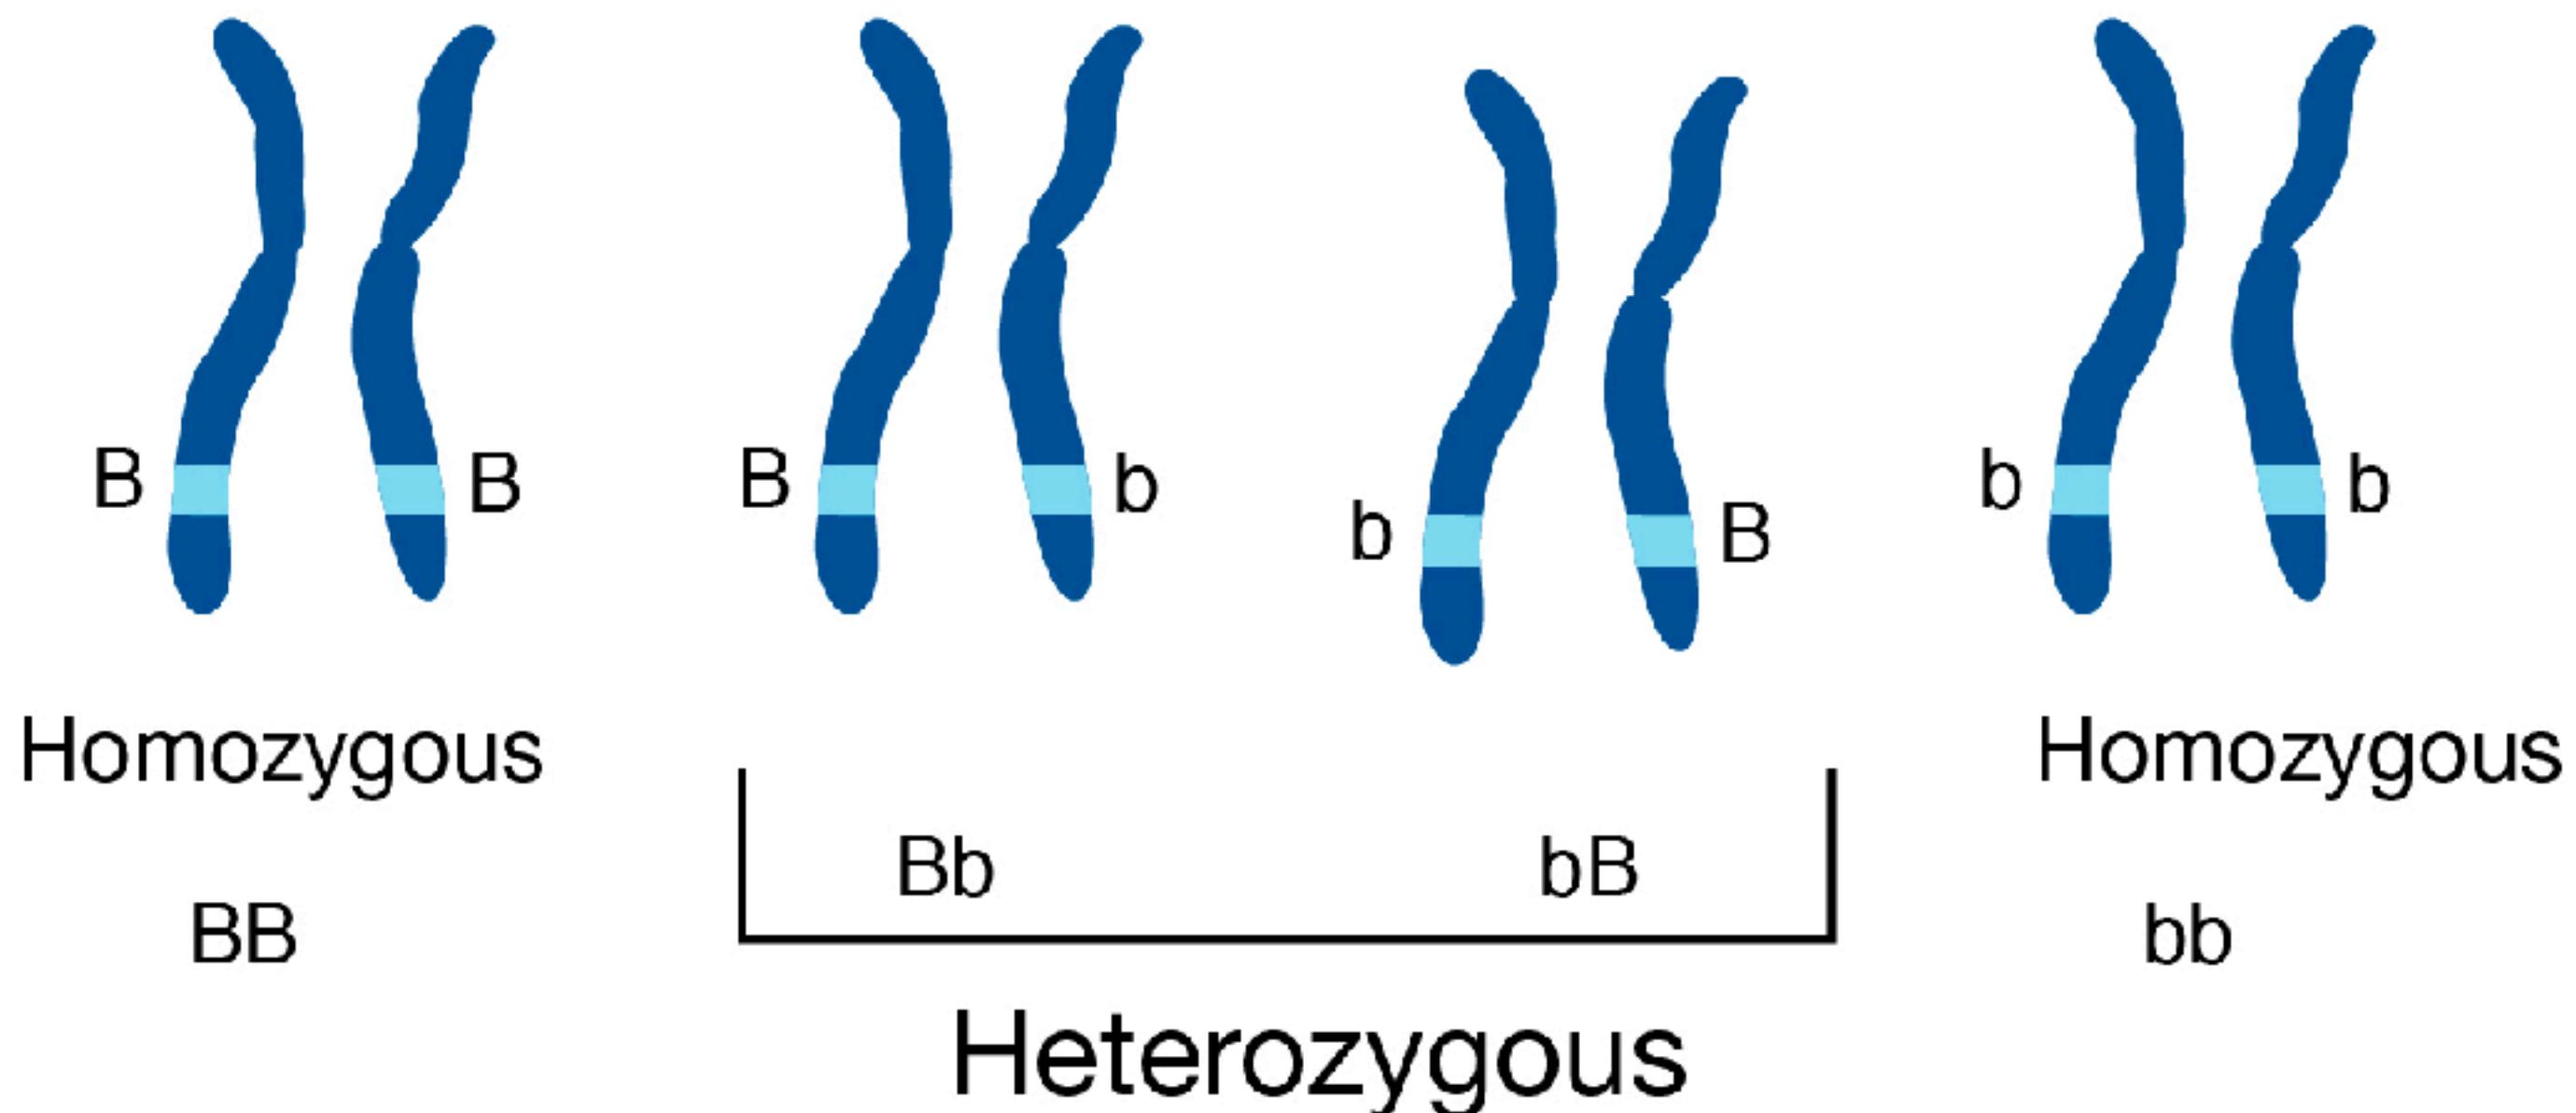

Homozygote vs. heterozygote

One copy from maternal genome
another copy from paternal genome

Homozygous: the maternal == paternal copy

Heterozygous: the maternal != paternal copy

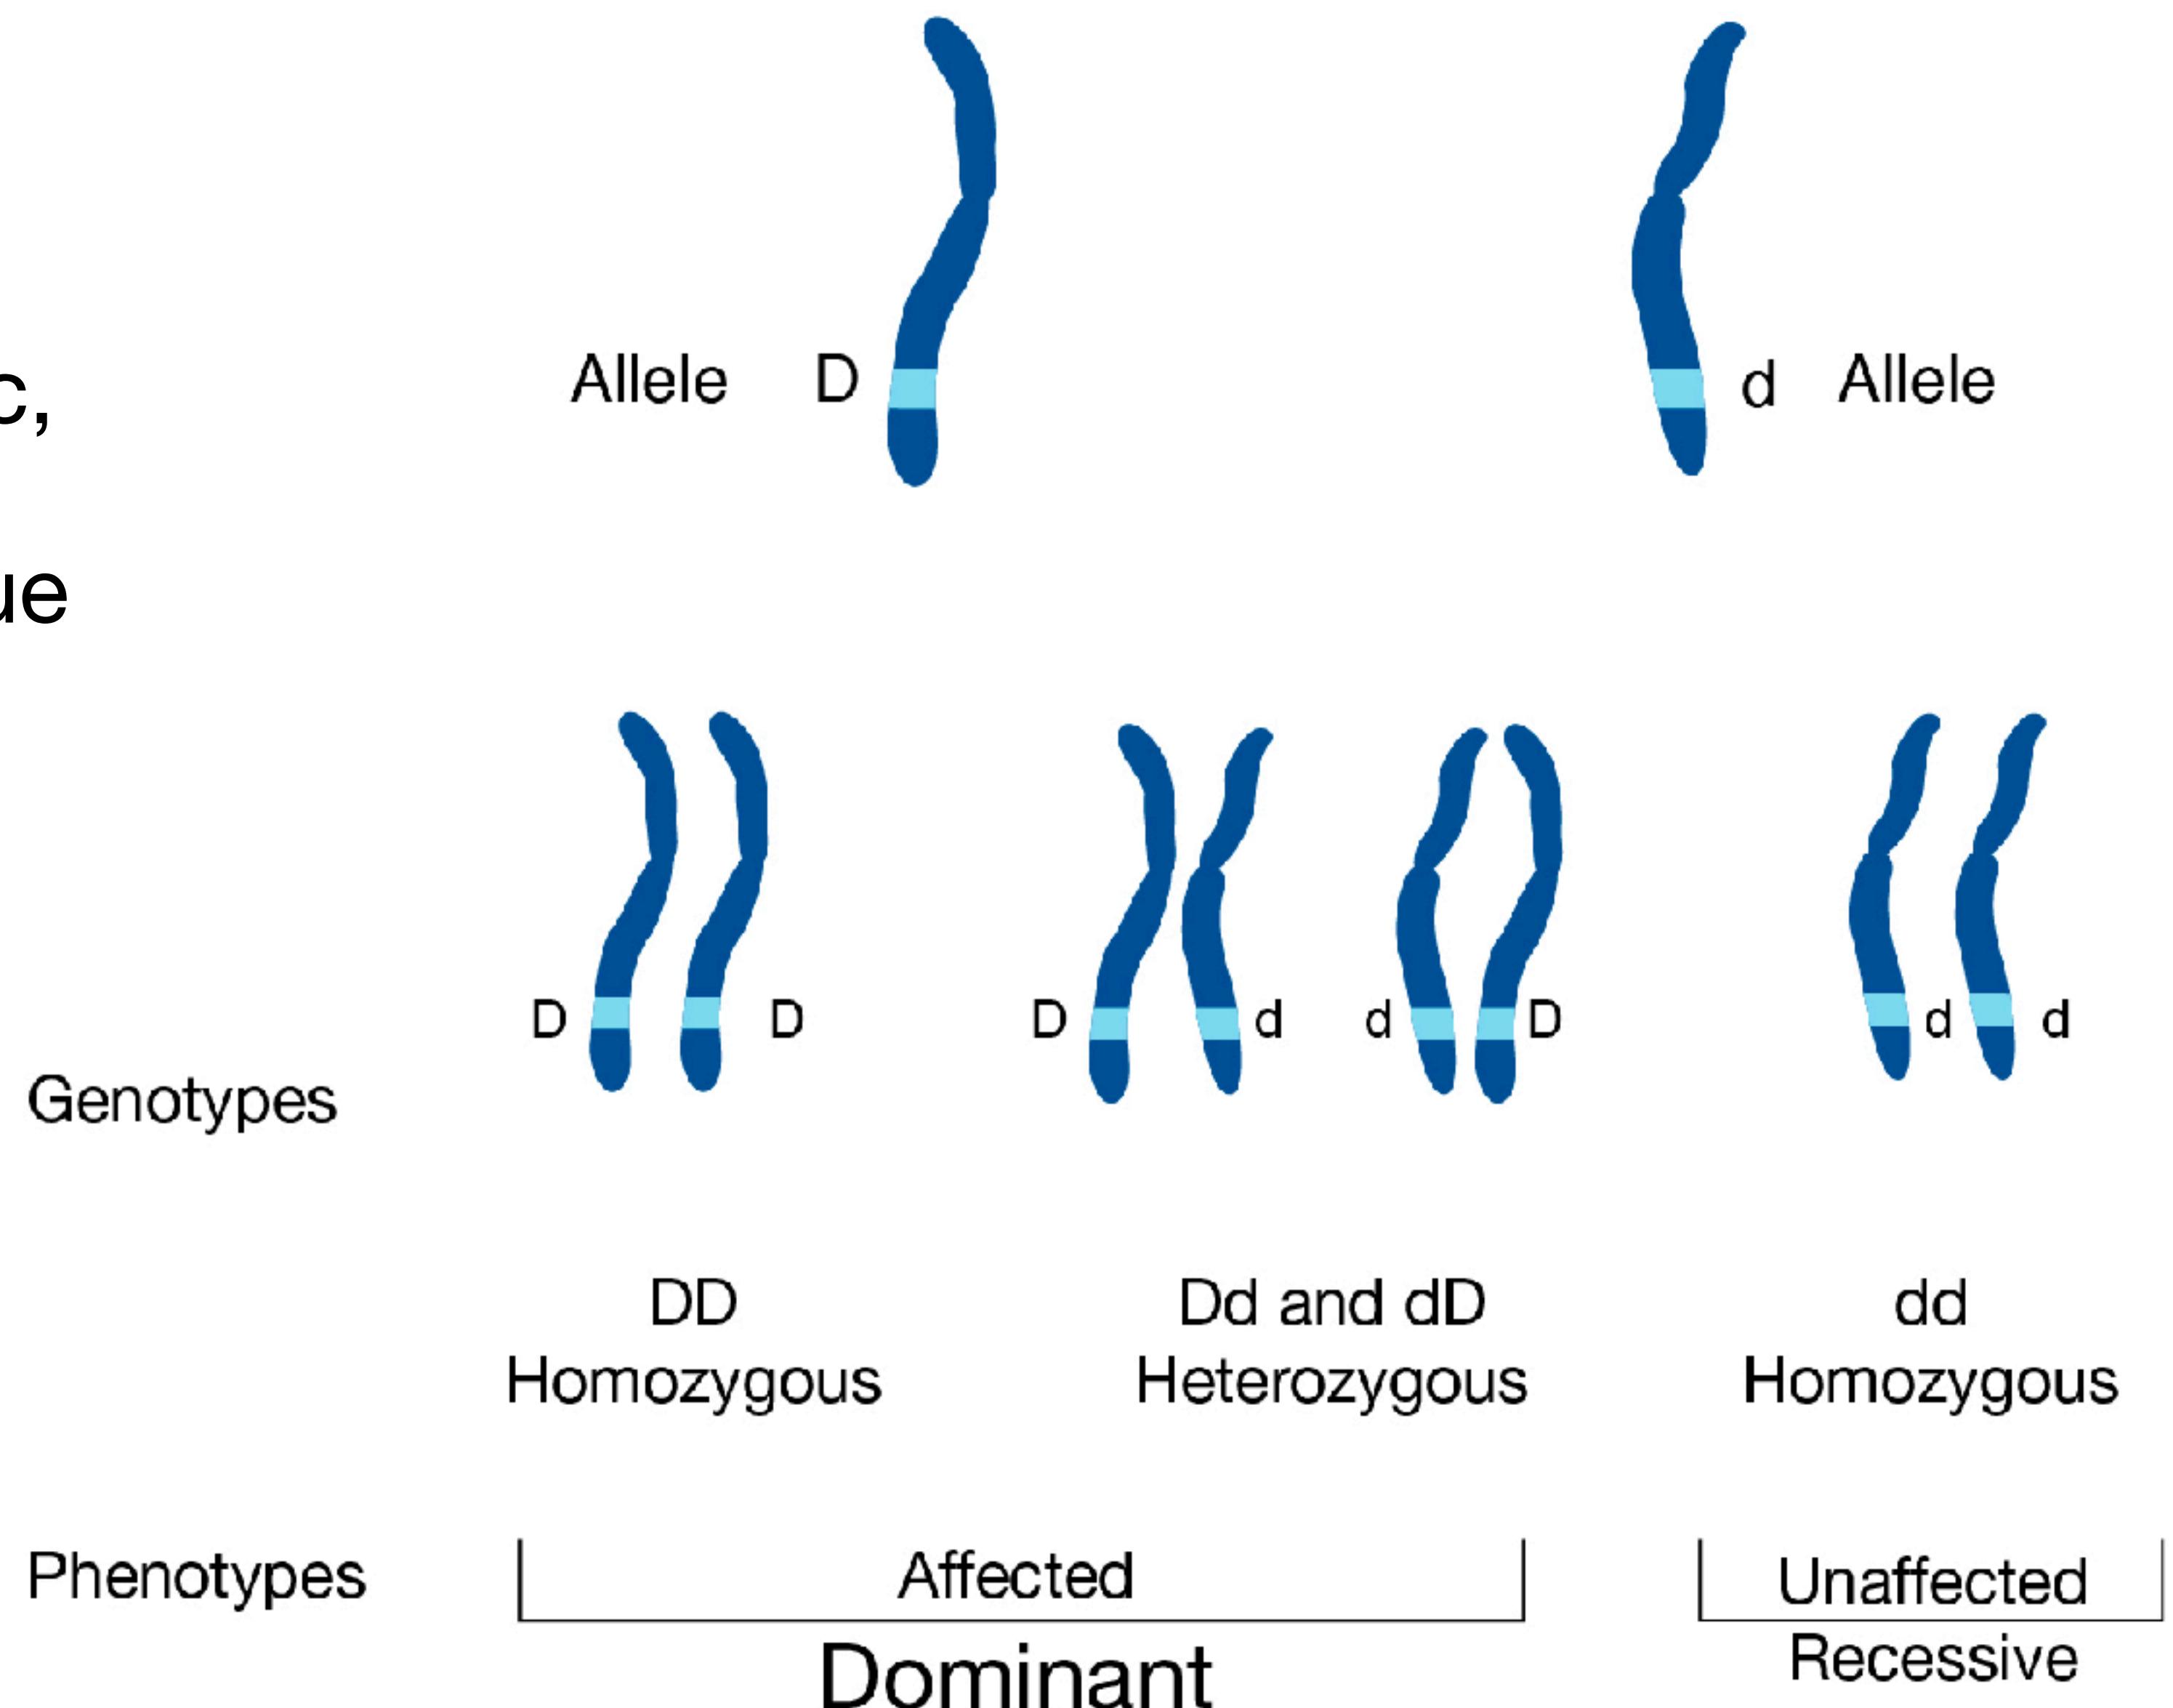

- "Homo" vs. "hetero" \iff the same vs. different
- Zygote (fertilized egg cell)

Huntington's Disease

Dominance

If one allele of a gene is toxic,
the other allele of the same,
wildtype gene may not rescue

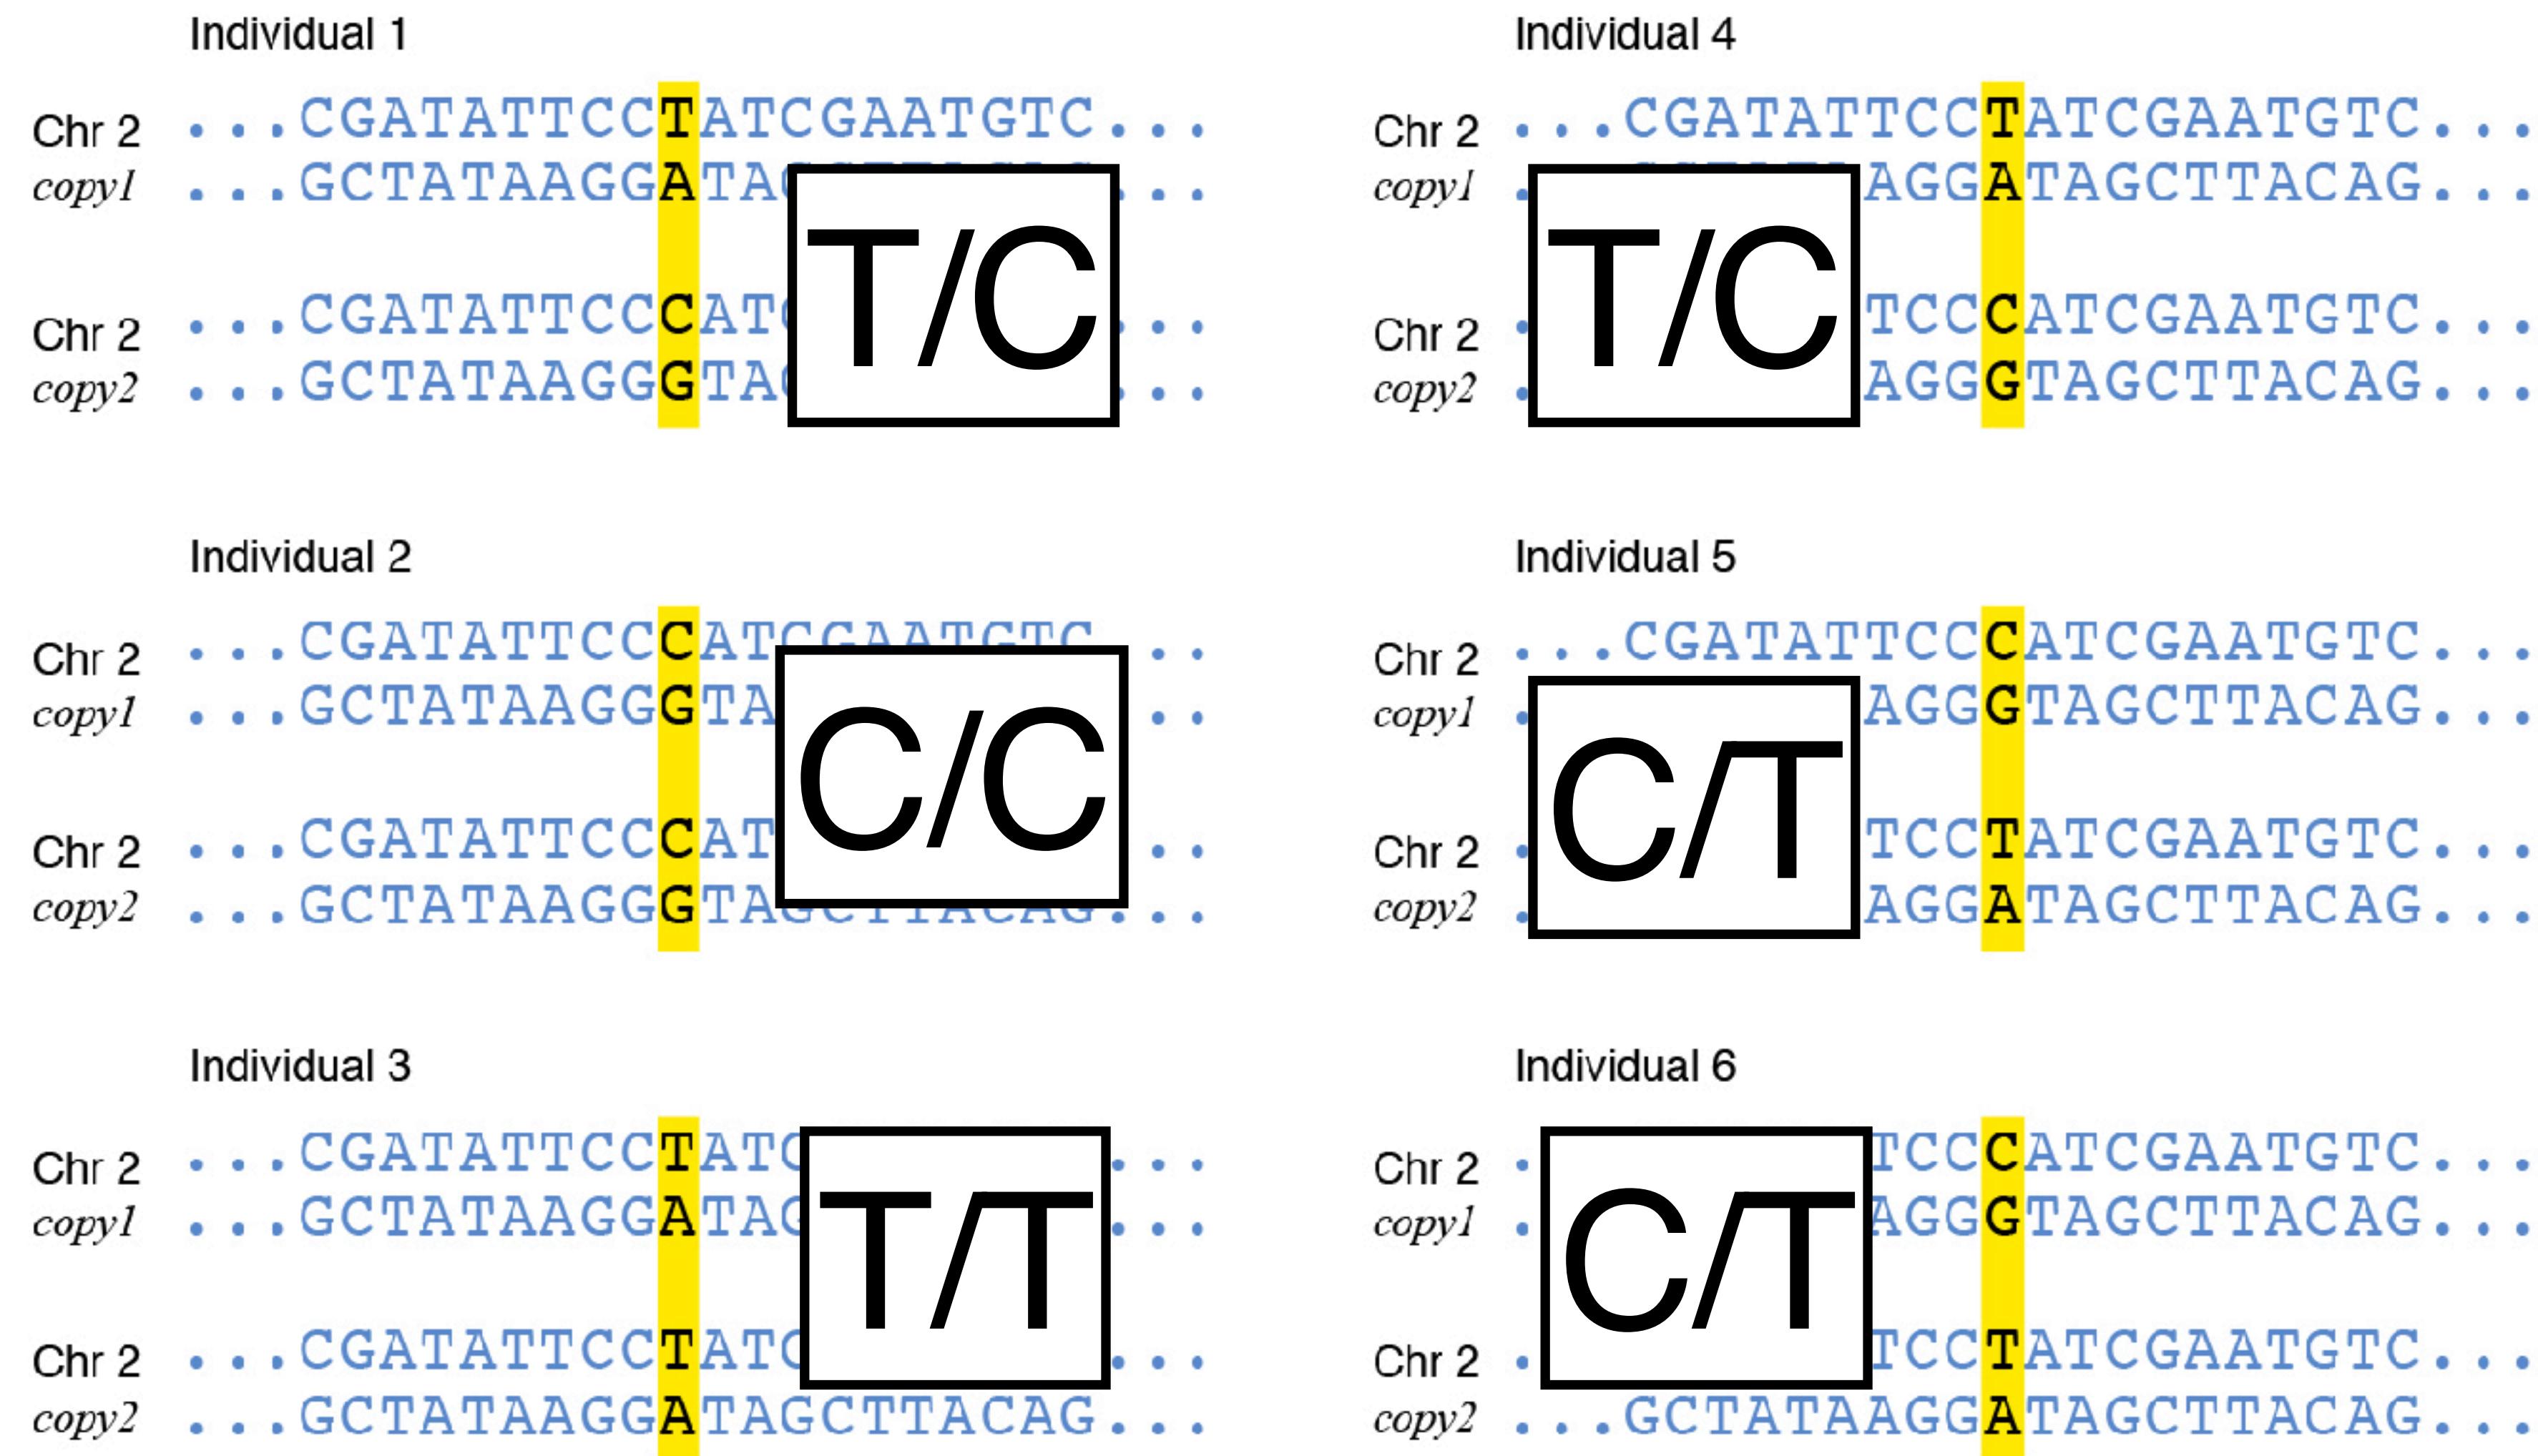

Single Nucleotide Polymorphism

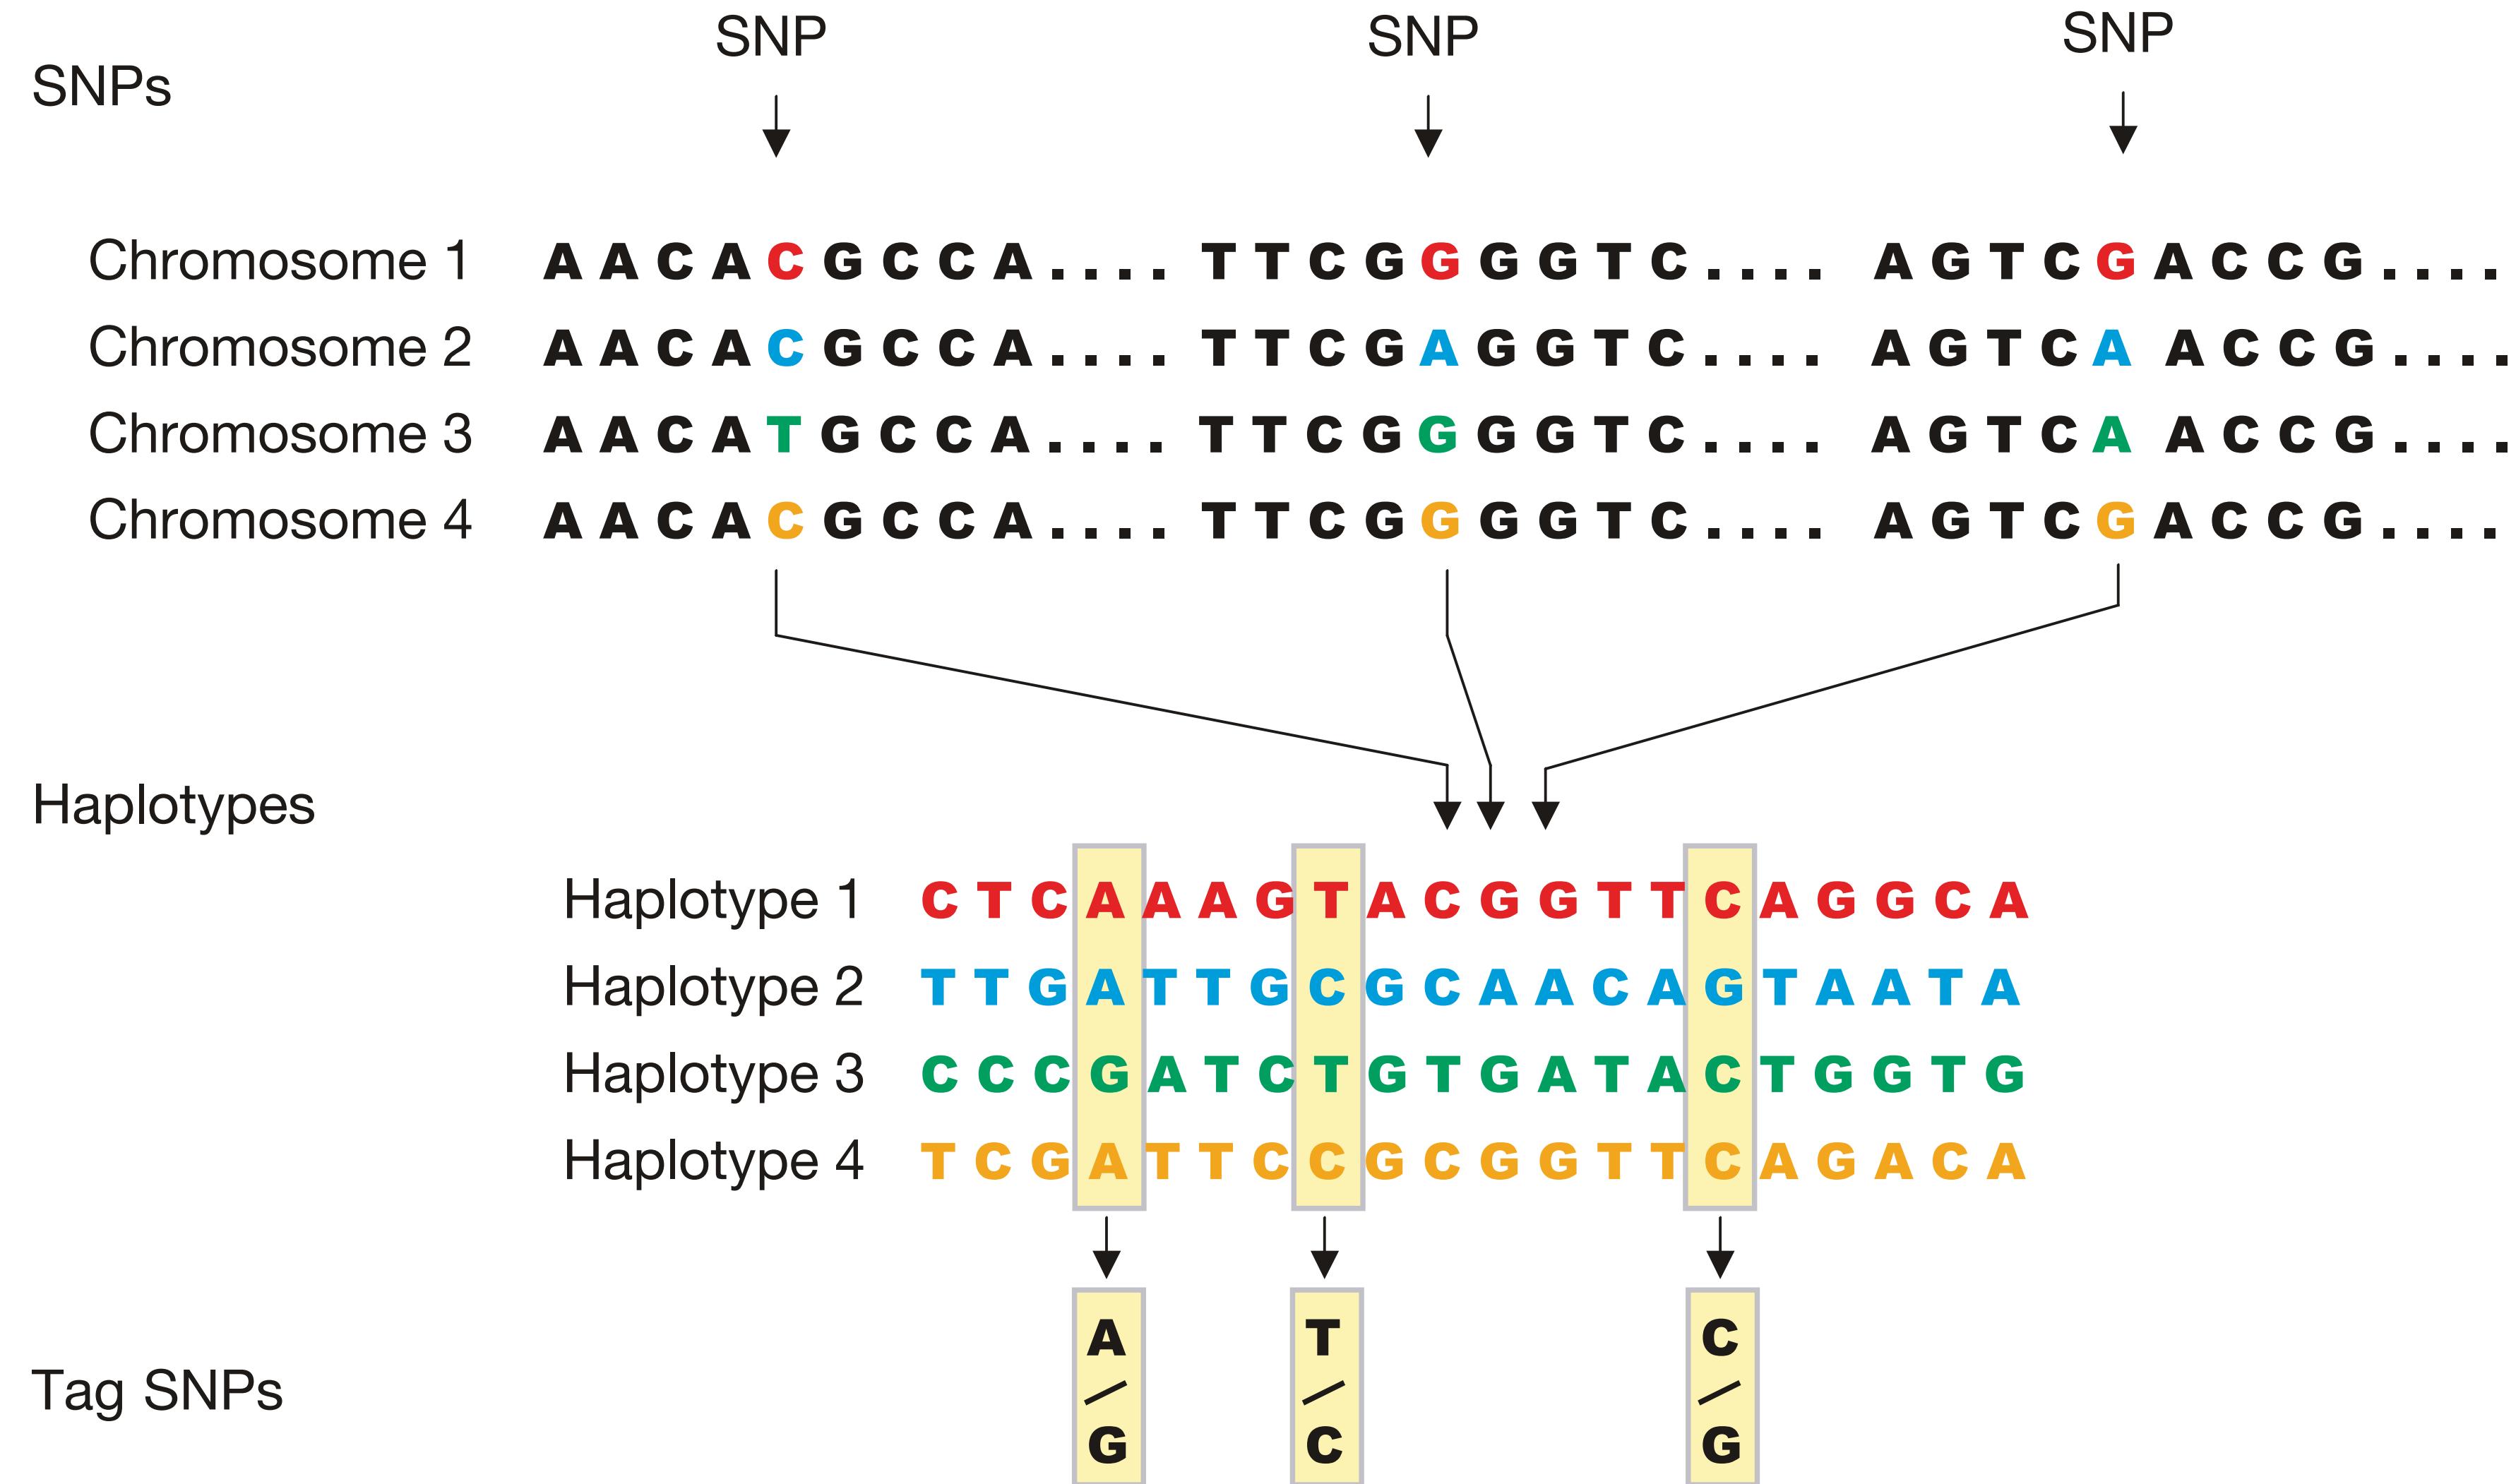

Single nucleotide polymorphism is way too many syllables, so you can understand why we just say "snip". And this is really a simple concept.

These are the places in the genome where people differ.

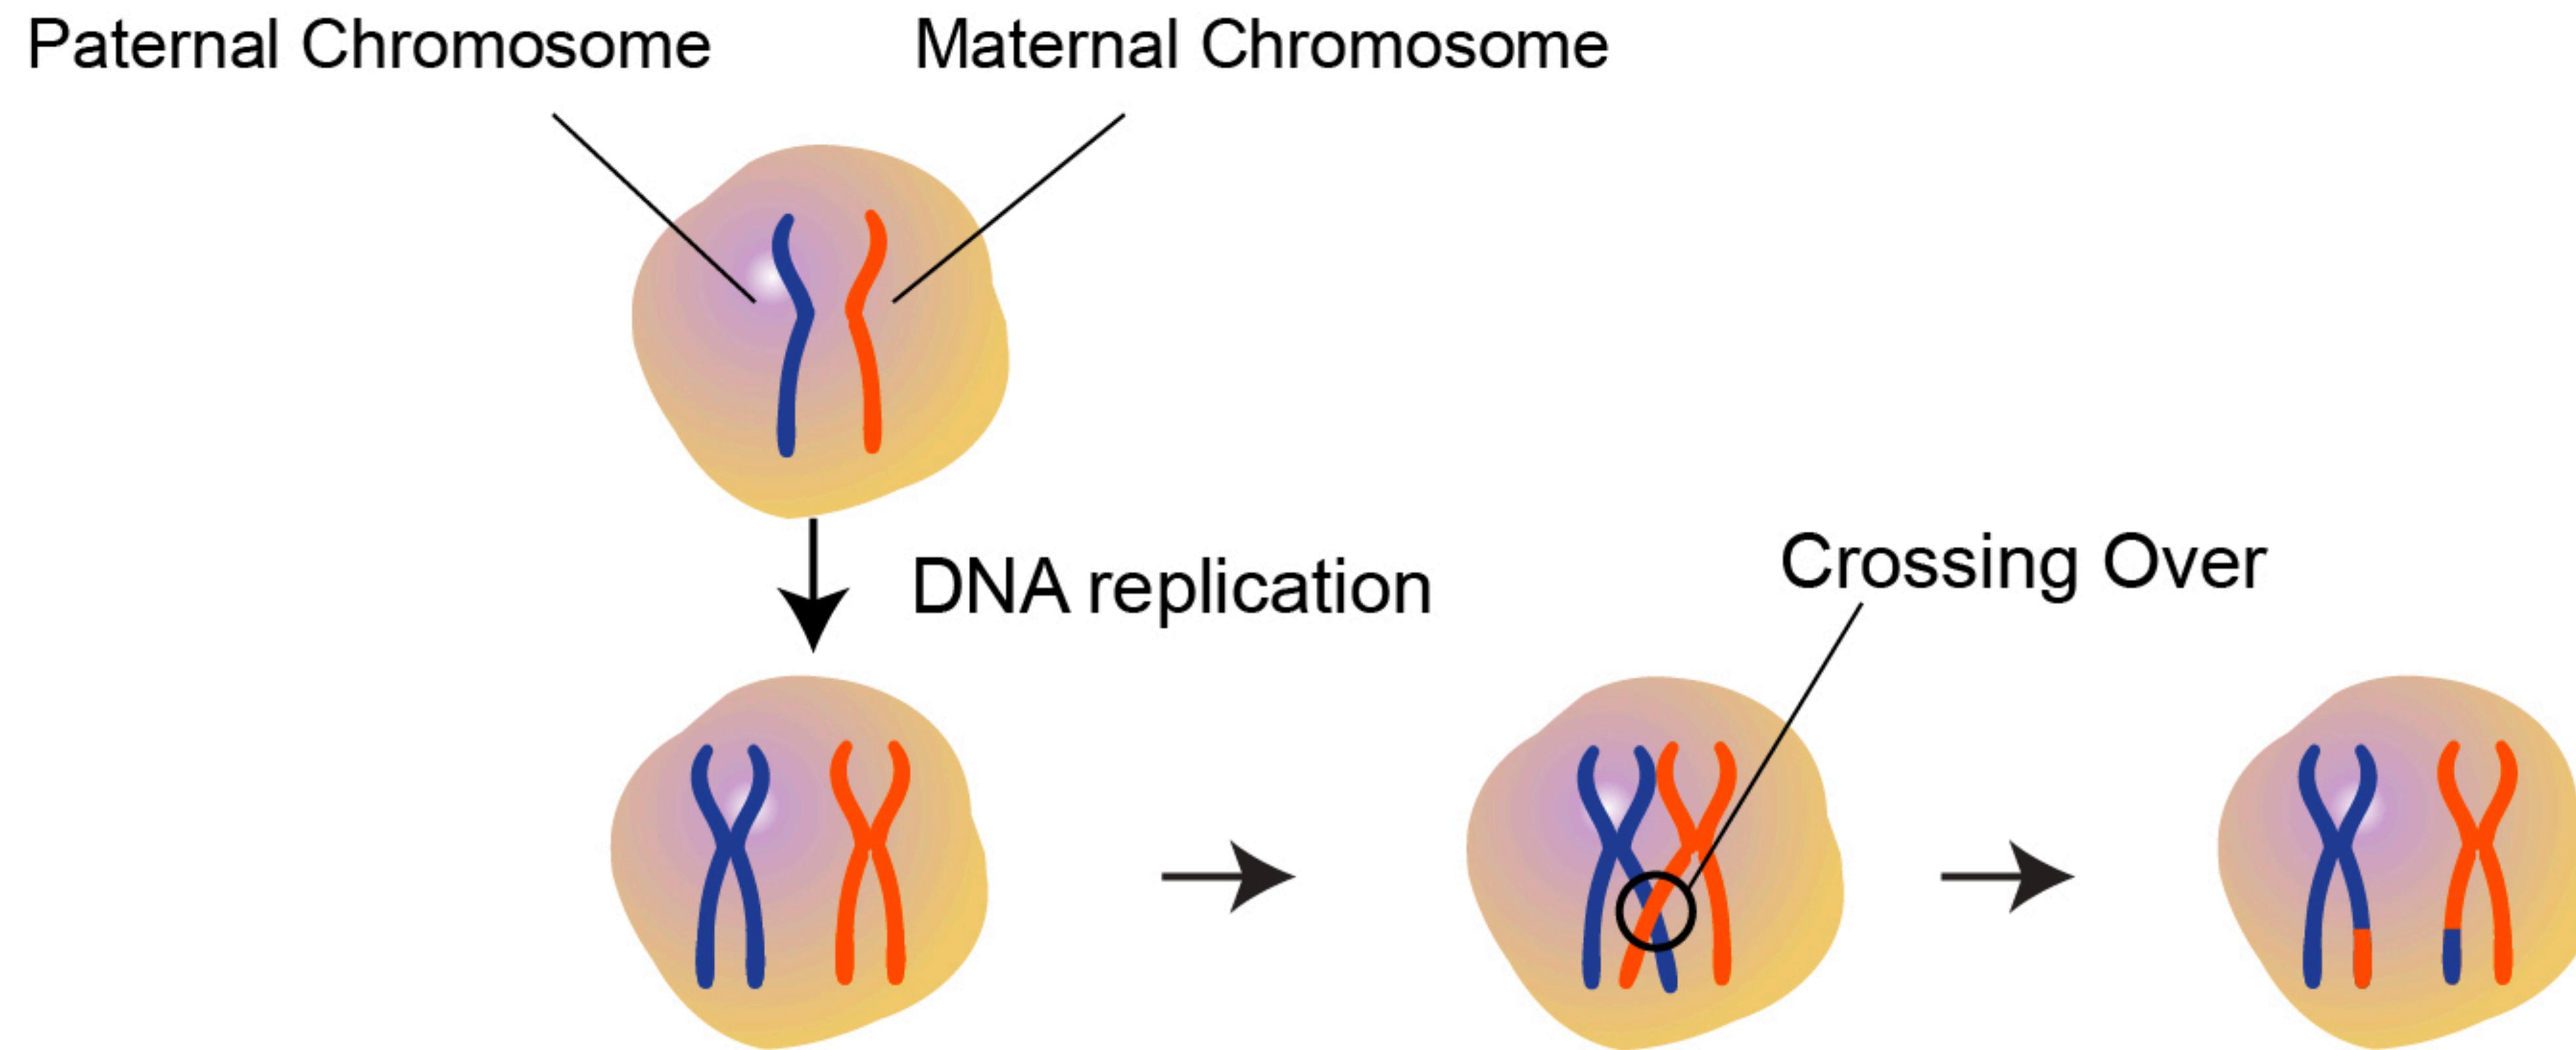

~1 in every 1000bp

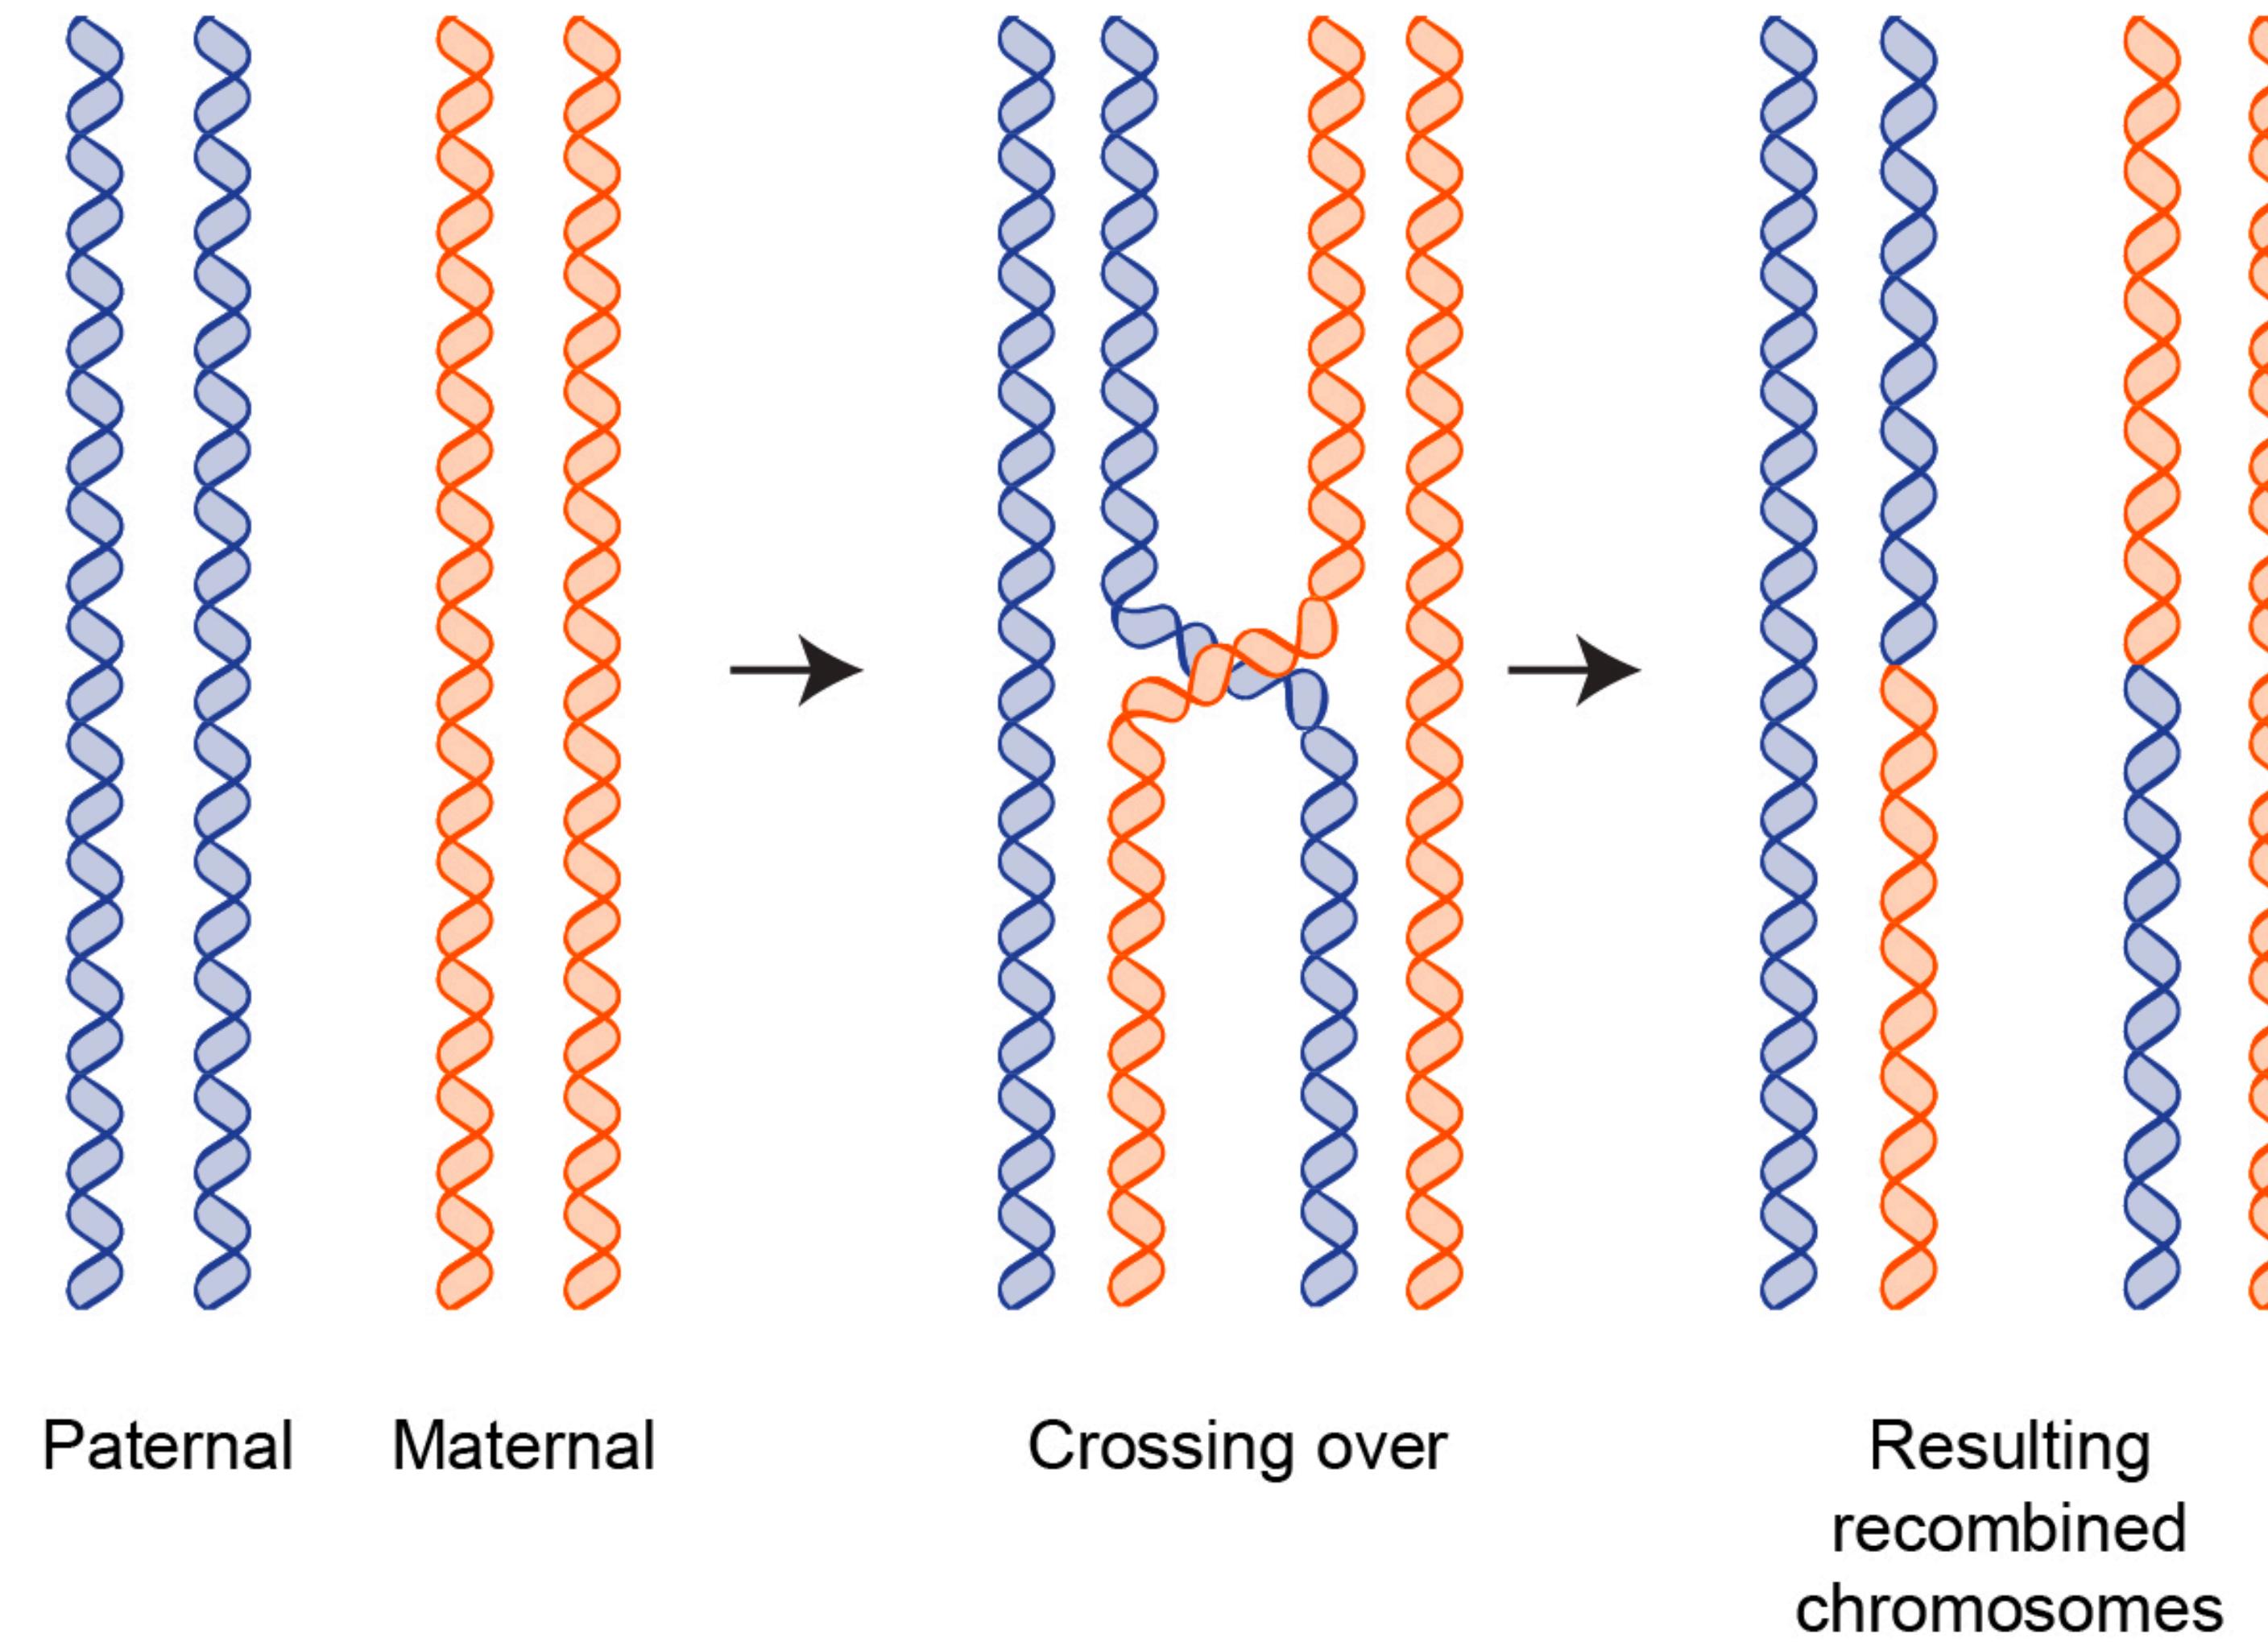

~ 1M common SNPs

Recombination: Mixing the maternal and paternal copies

How do we call/quantify variants?

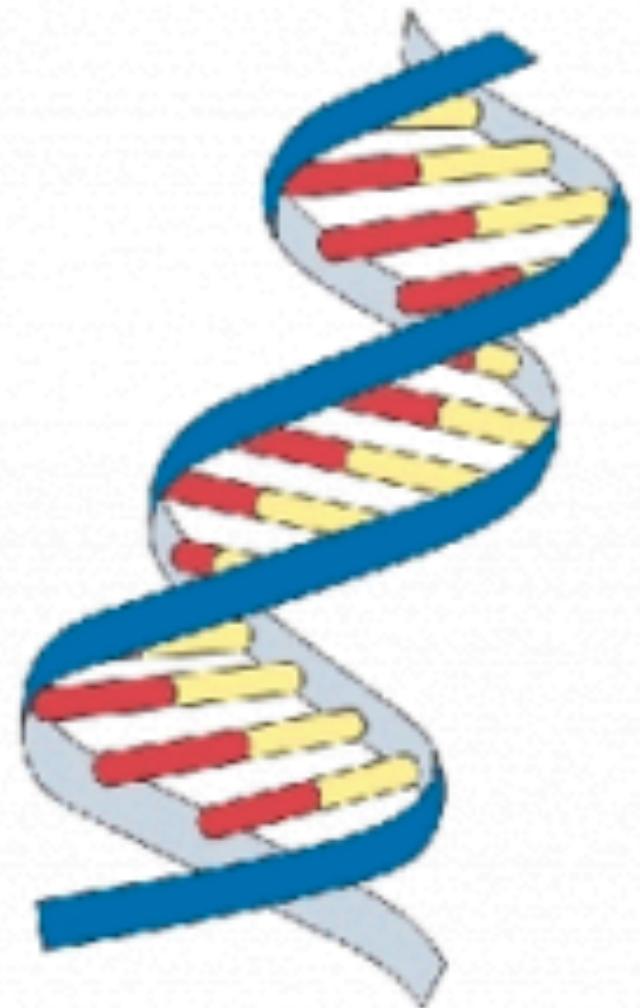

How do we measure variants?

<https://www.illumina.com/science/technology/microarray.html>

Genetic association studies: genotype vs. phenotype

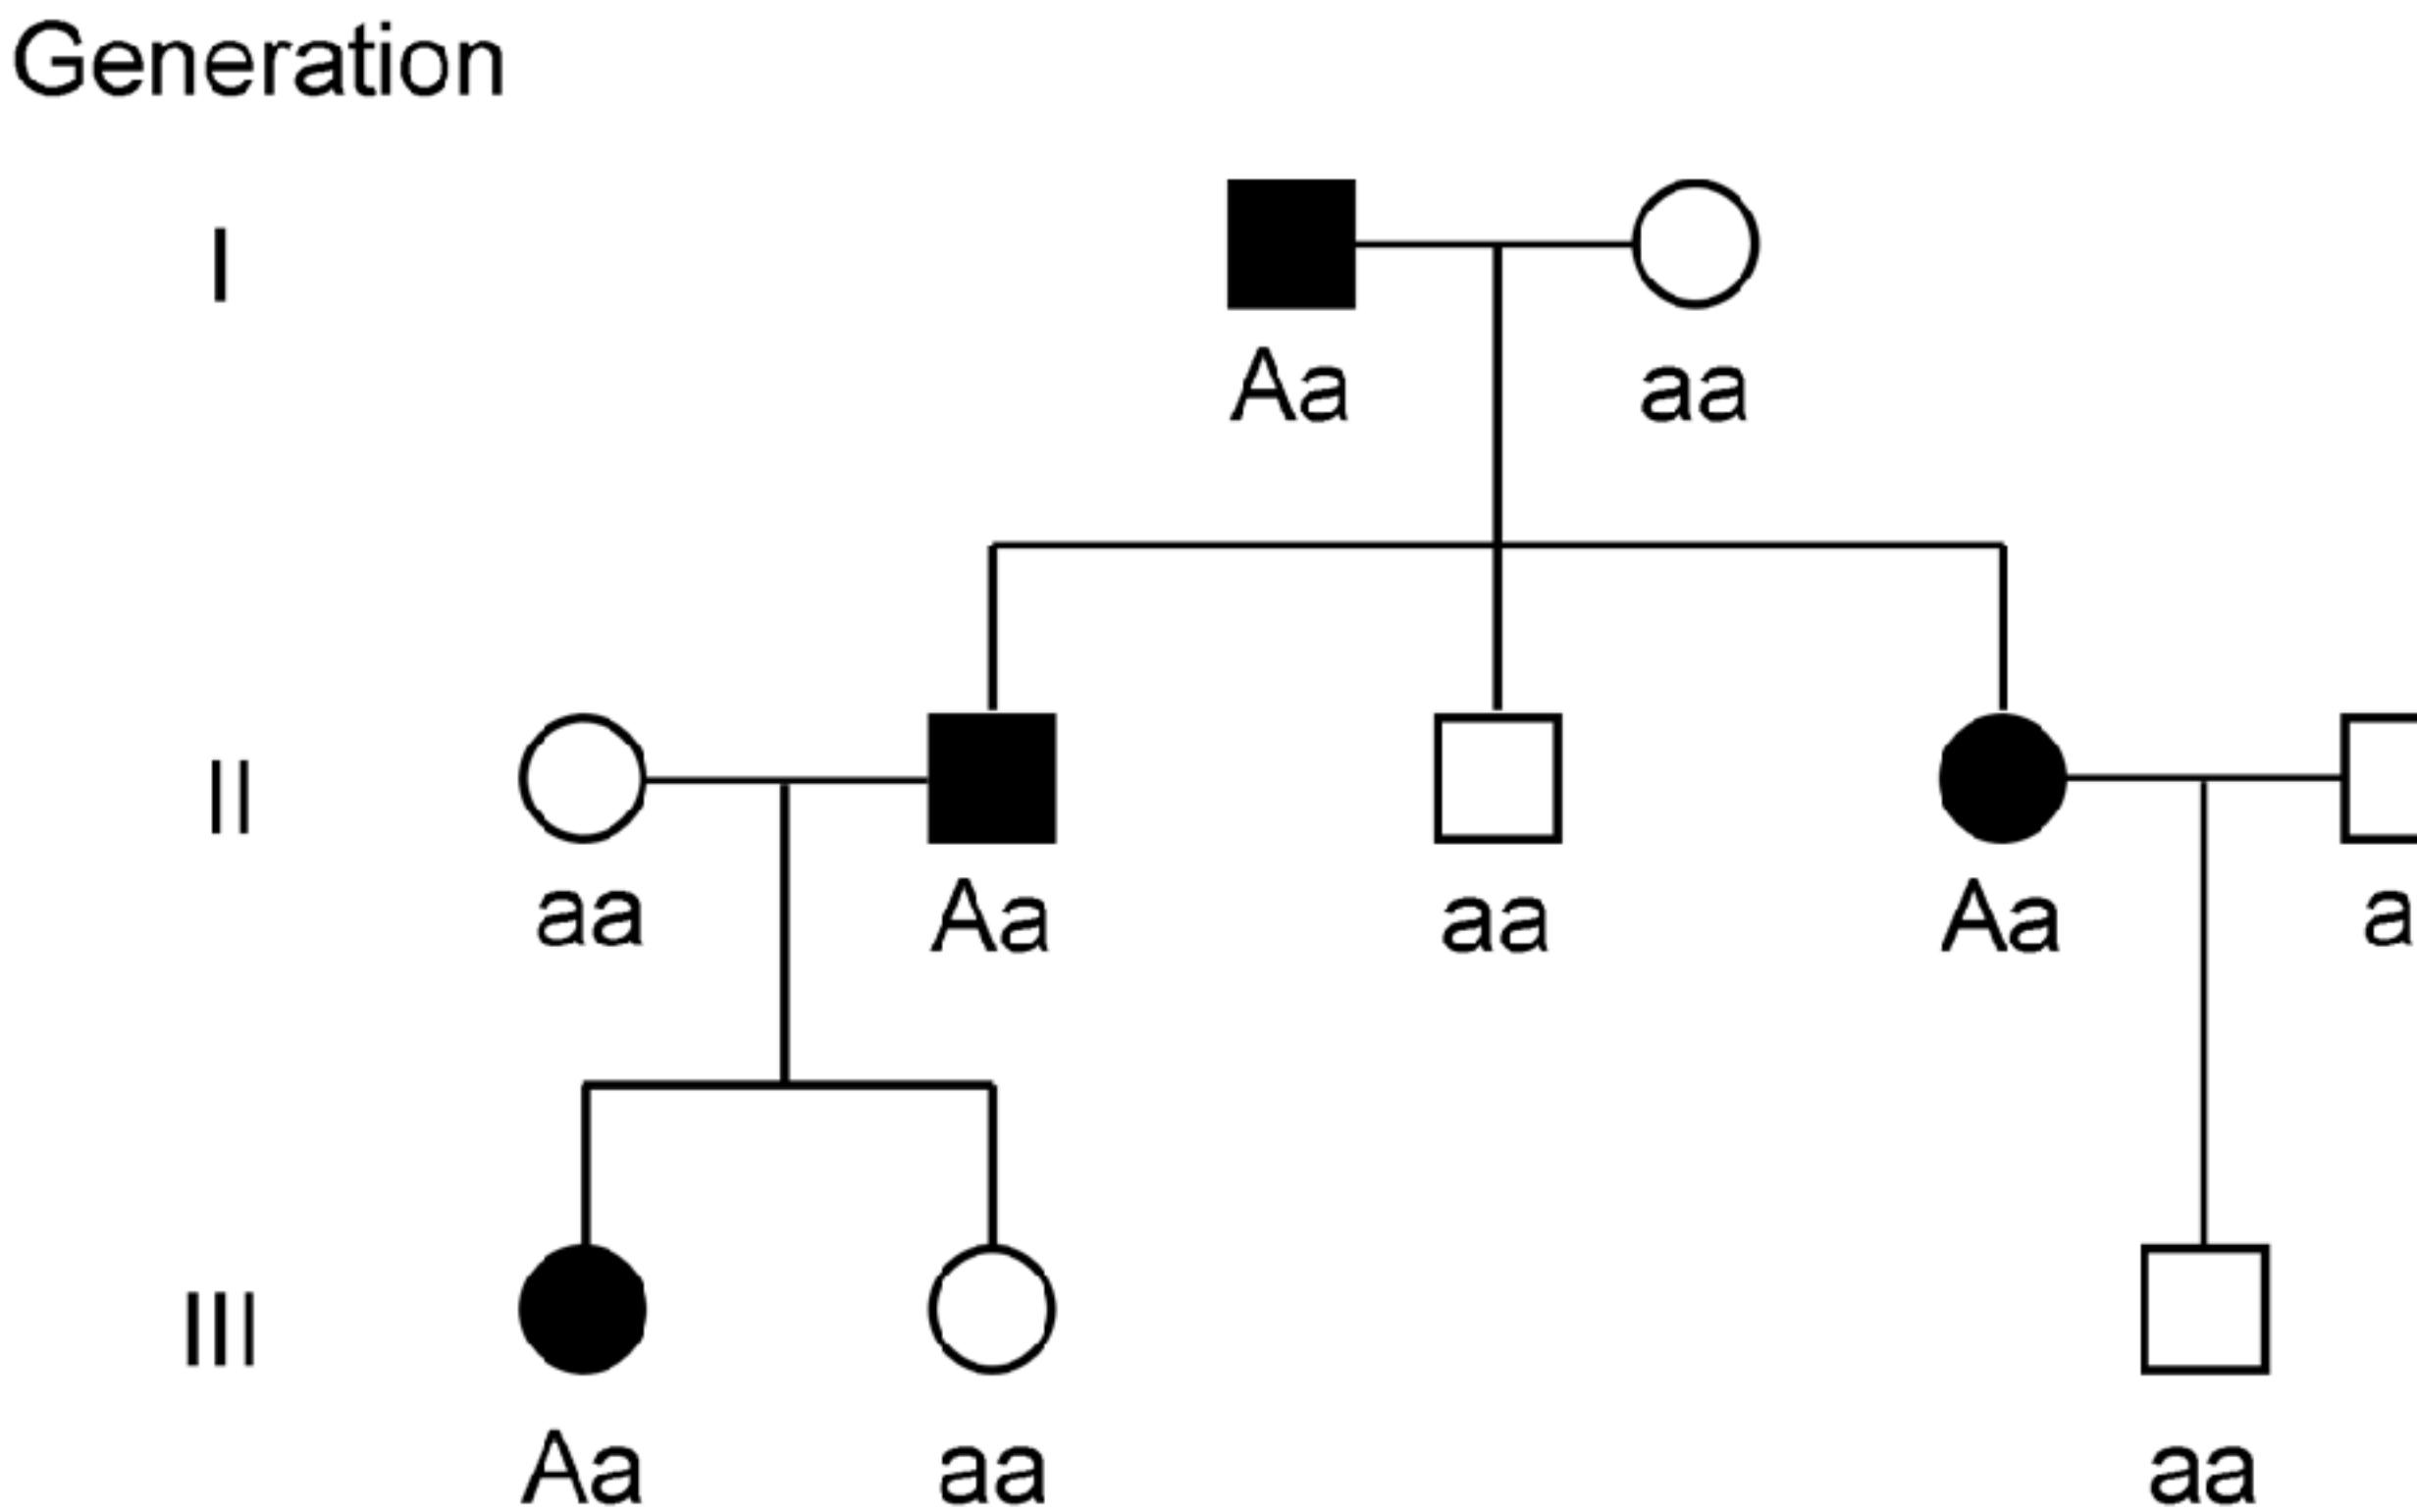

How do we test this?

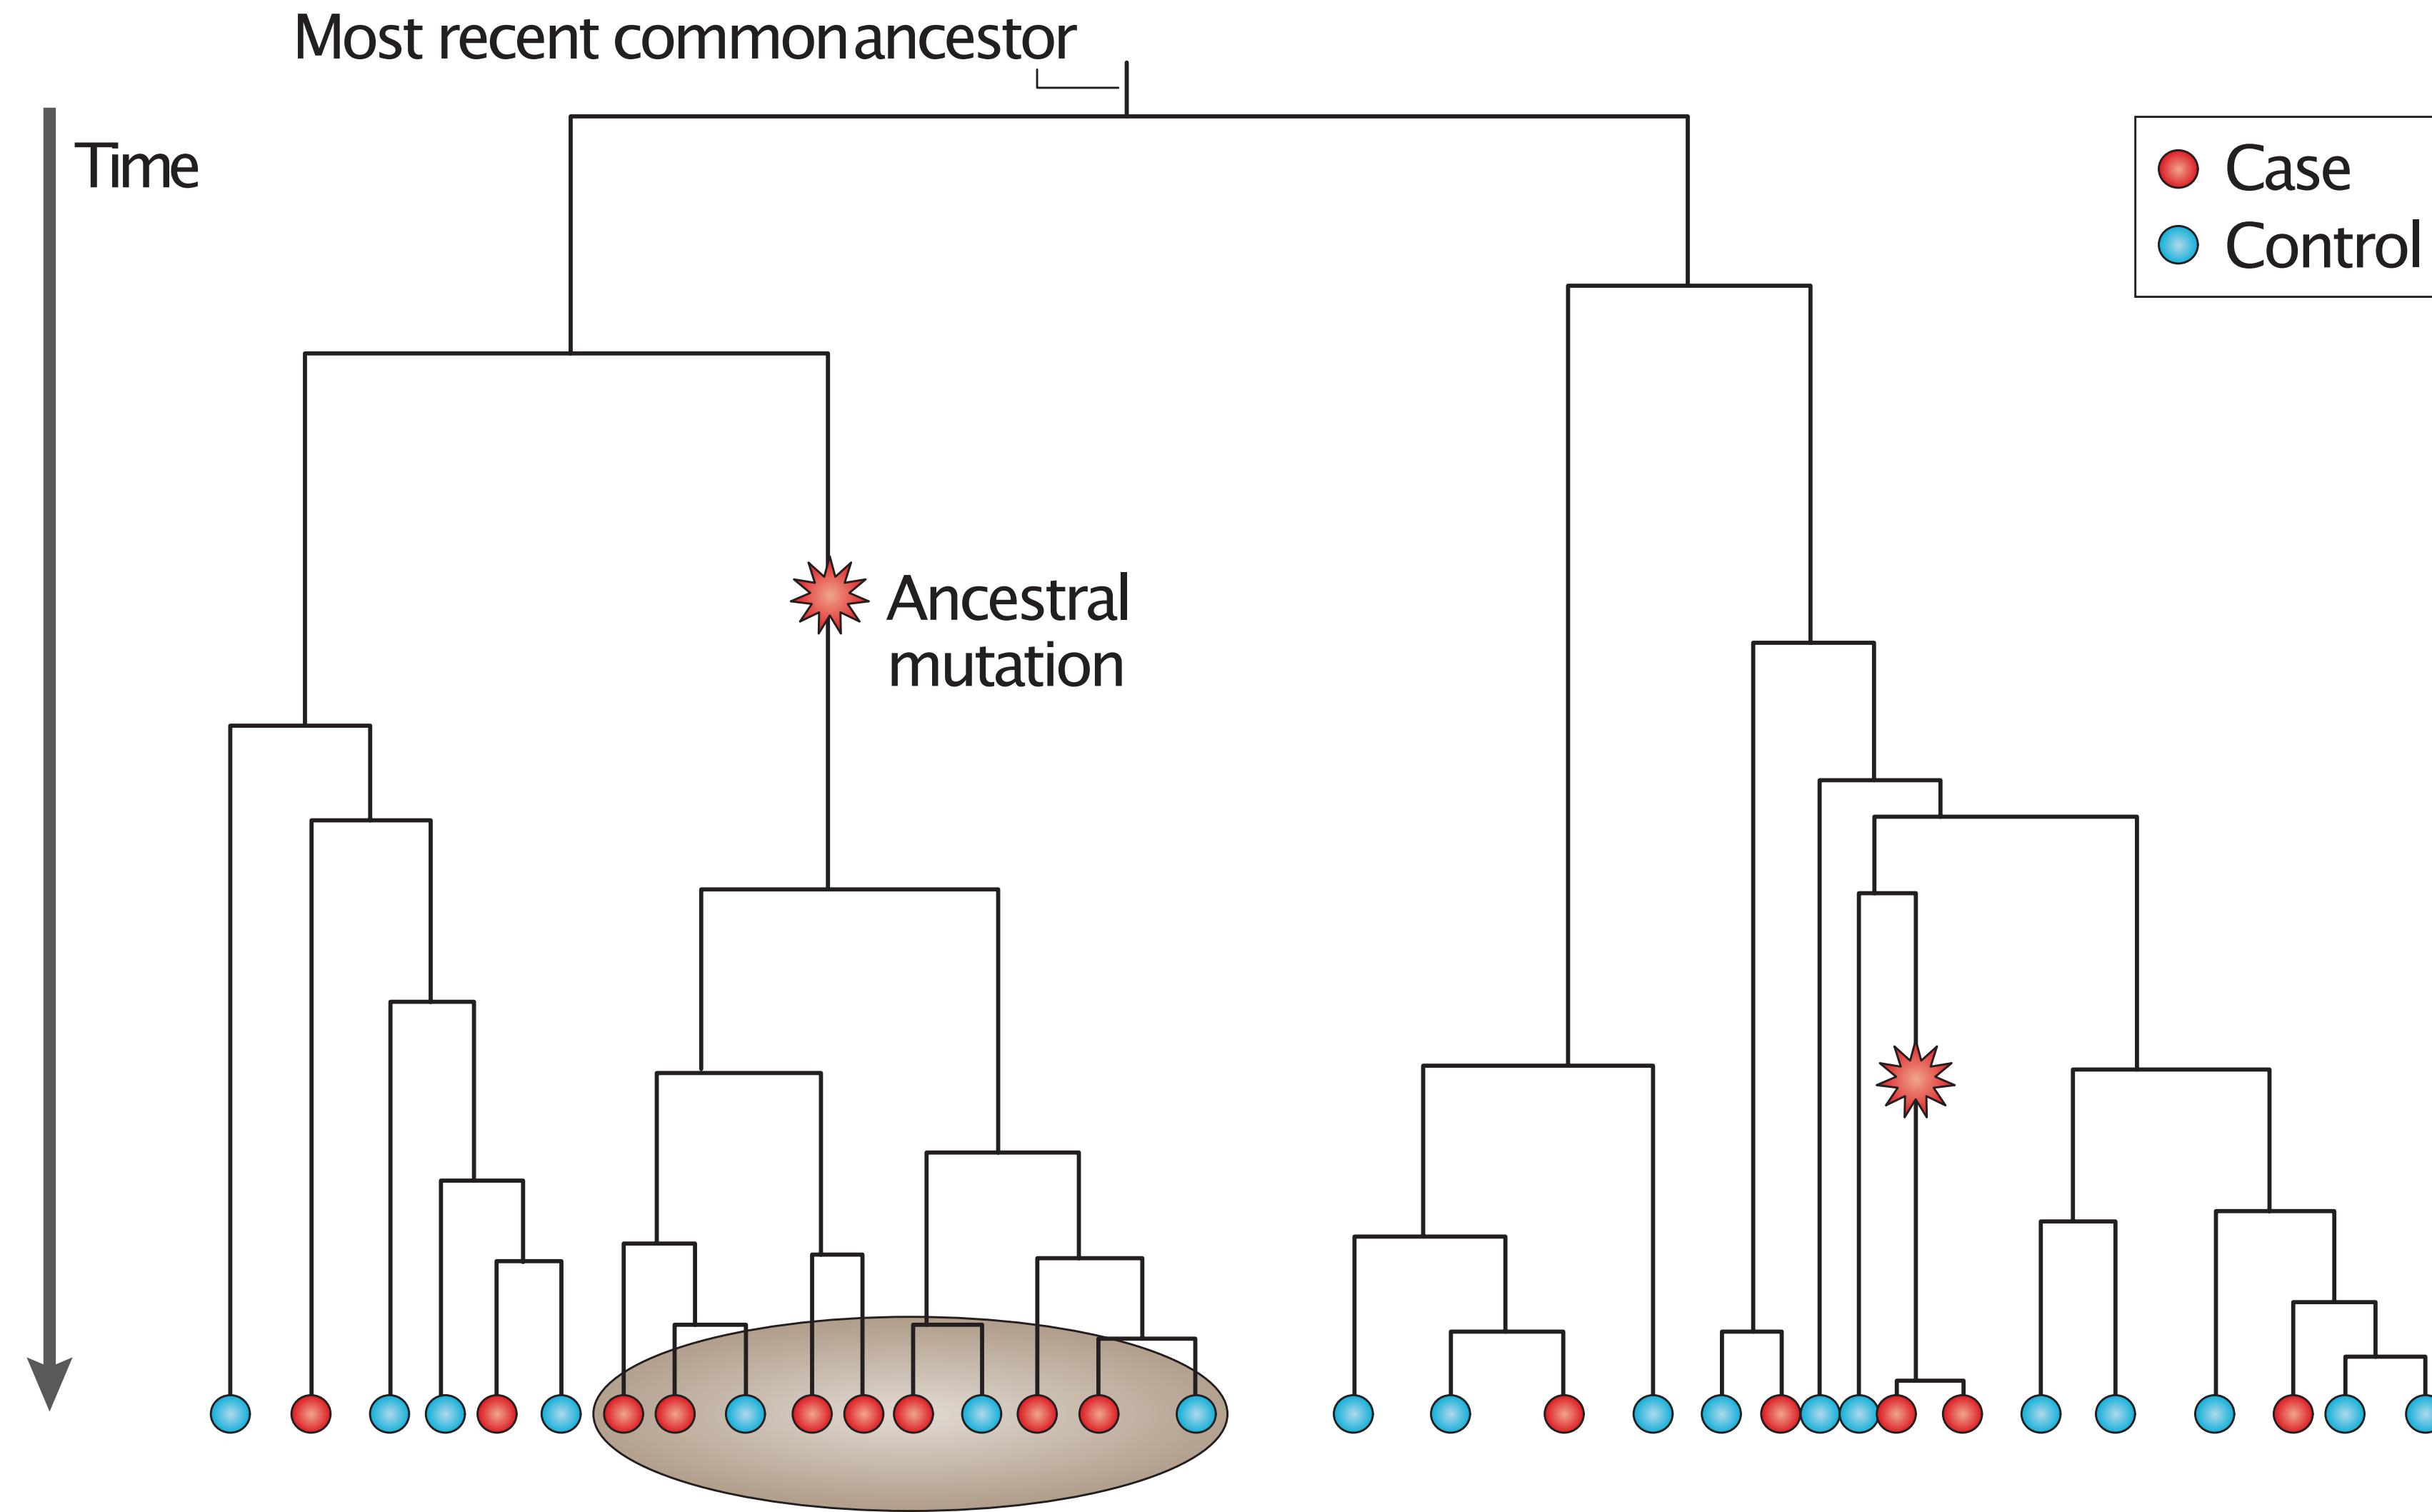

Genotypes are the genetic make-up of an individual.

Phenotypes are the physical traits and characteristics of an individual and are influenced by their genotype and the environment.

How do we associate genetic variants to traits?

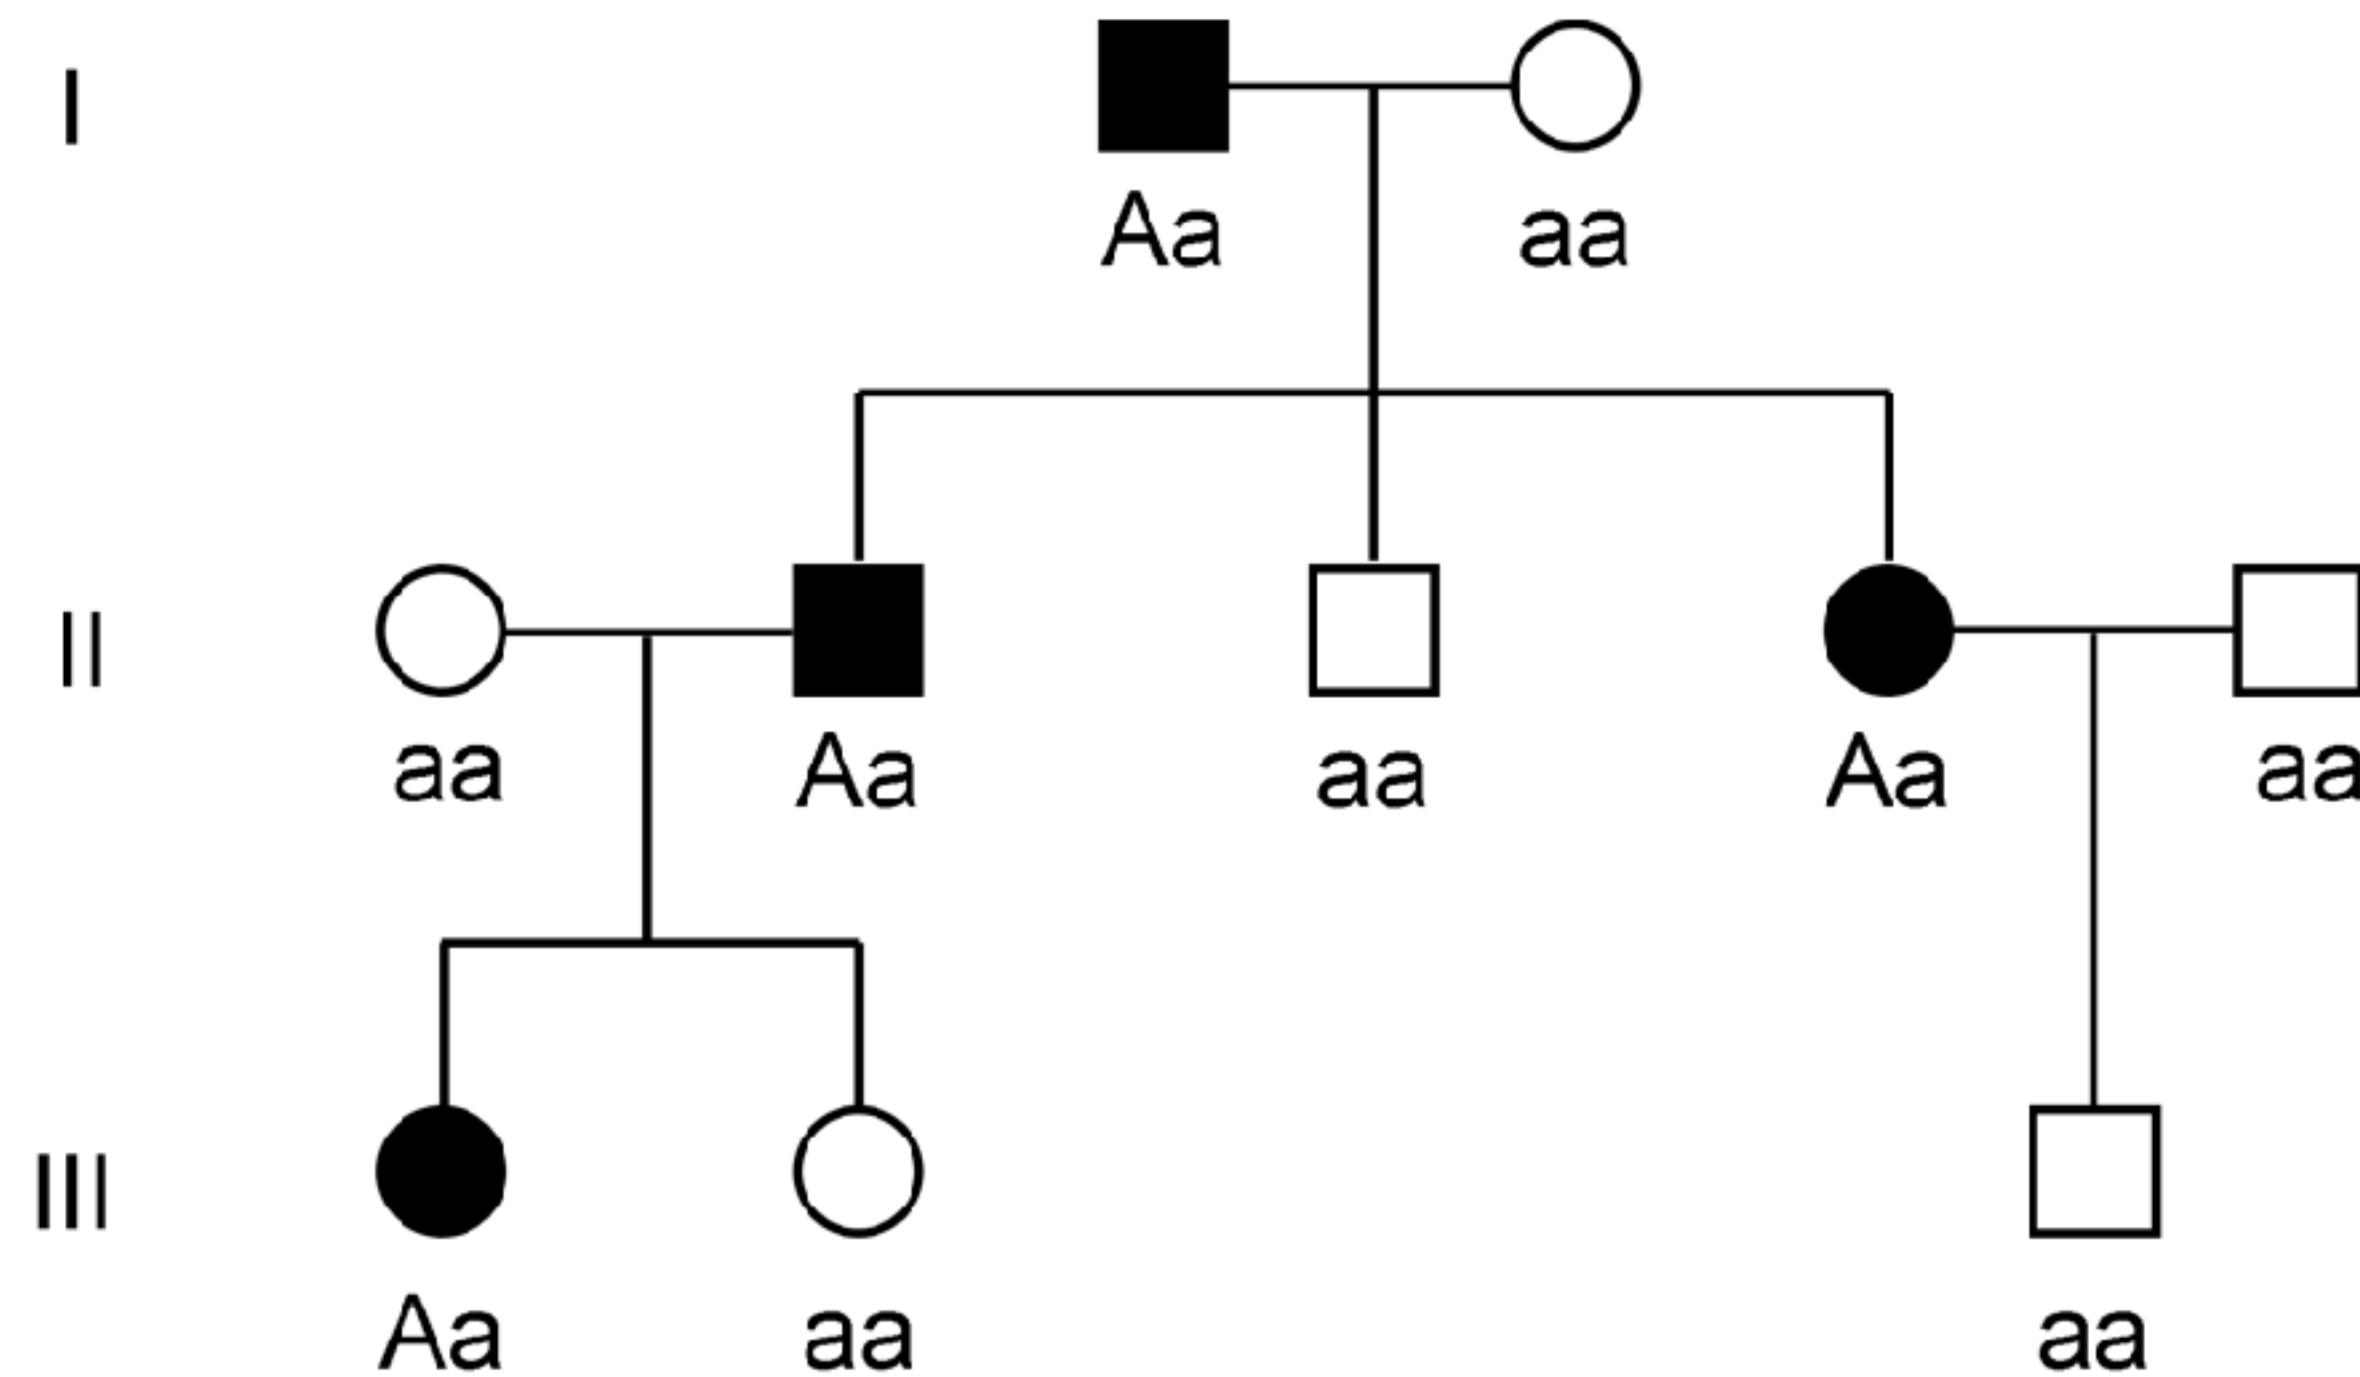

How can a genetic disease occur?

Mendelian disorders ≈ a single disease gene

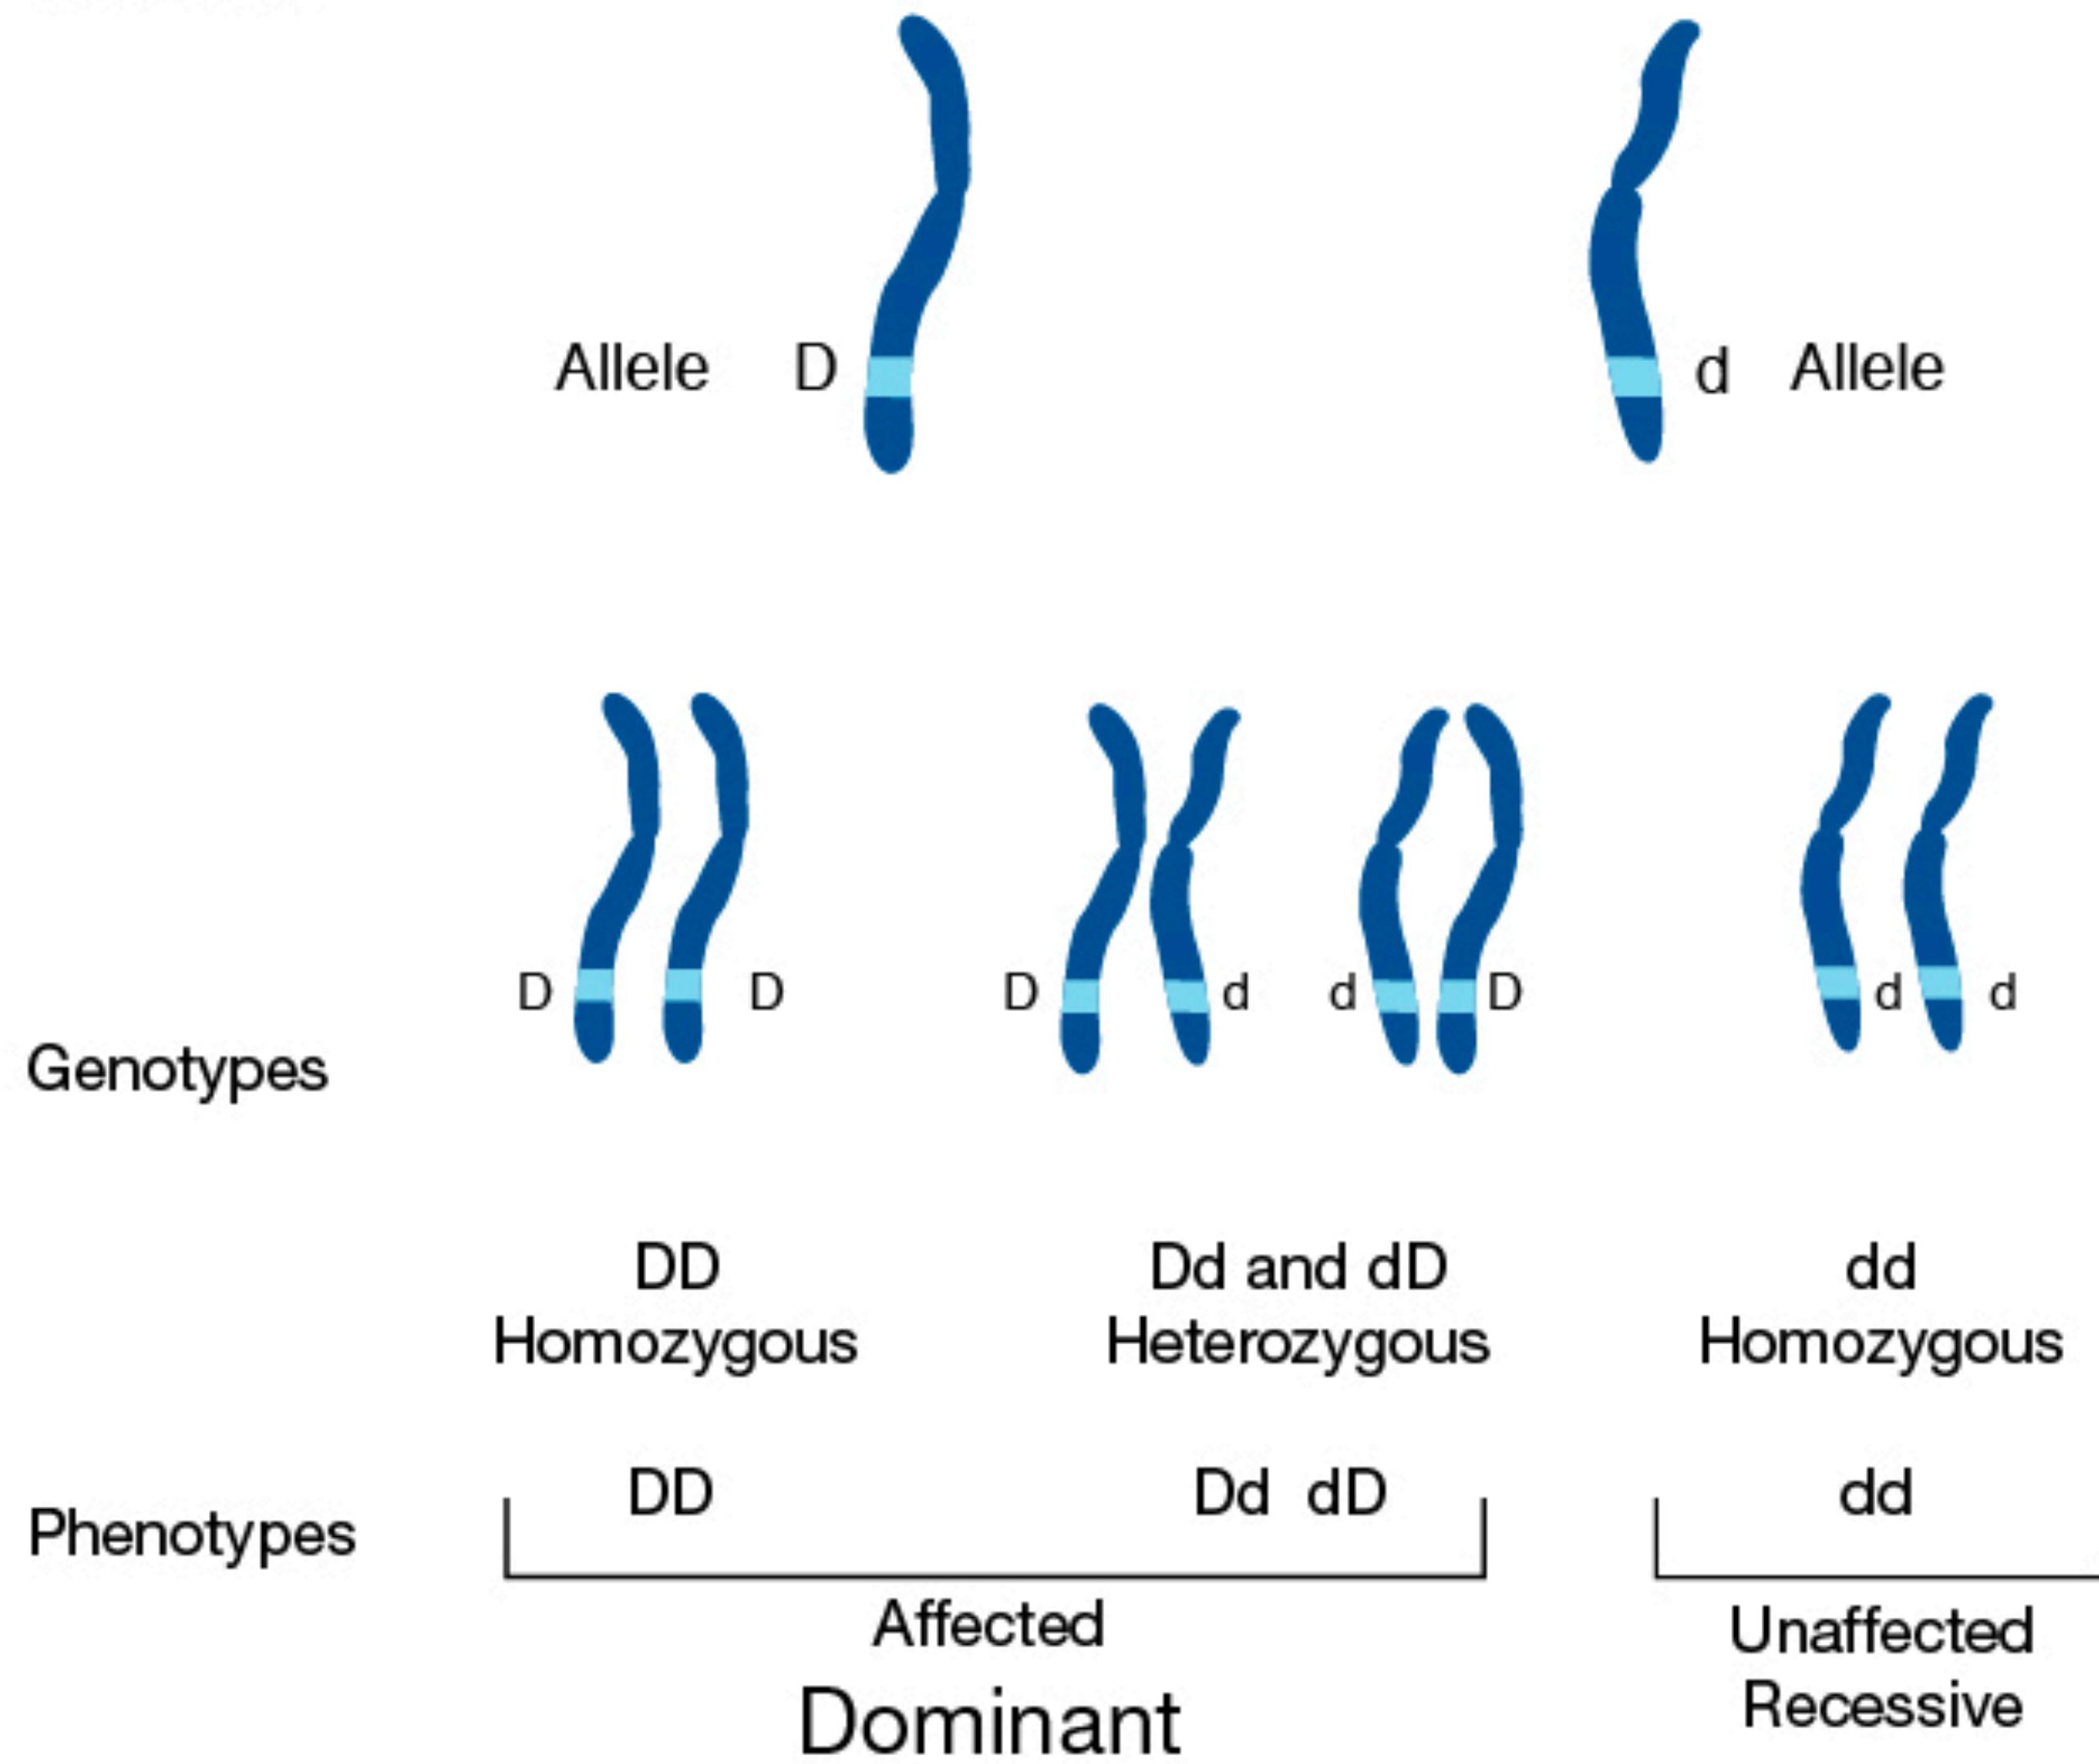

Generation

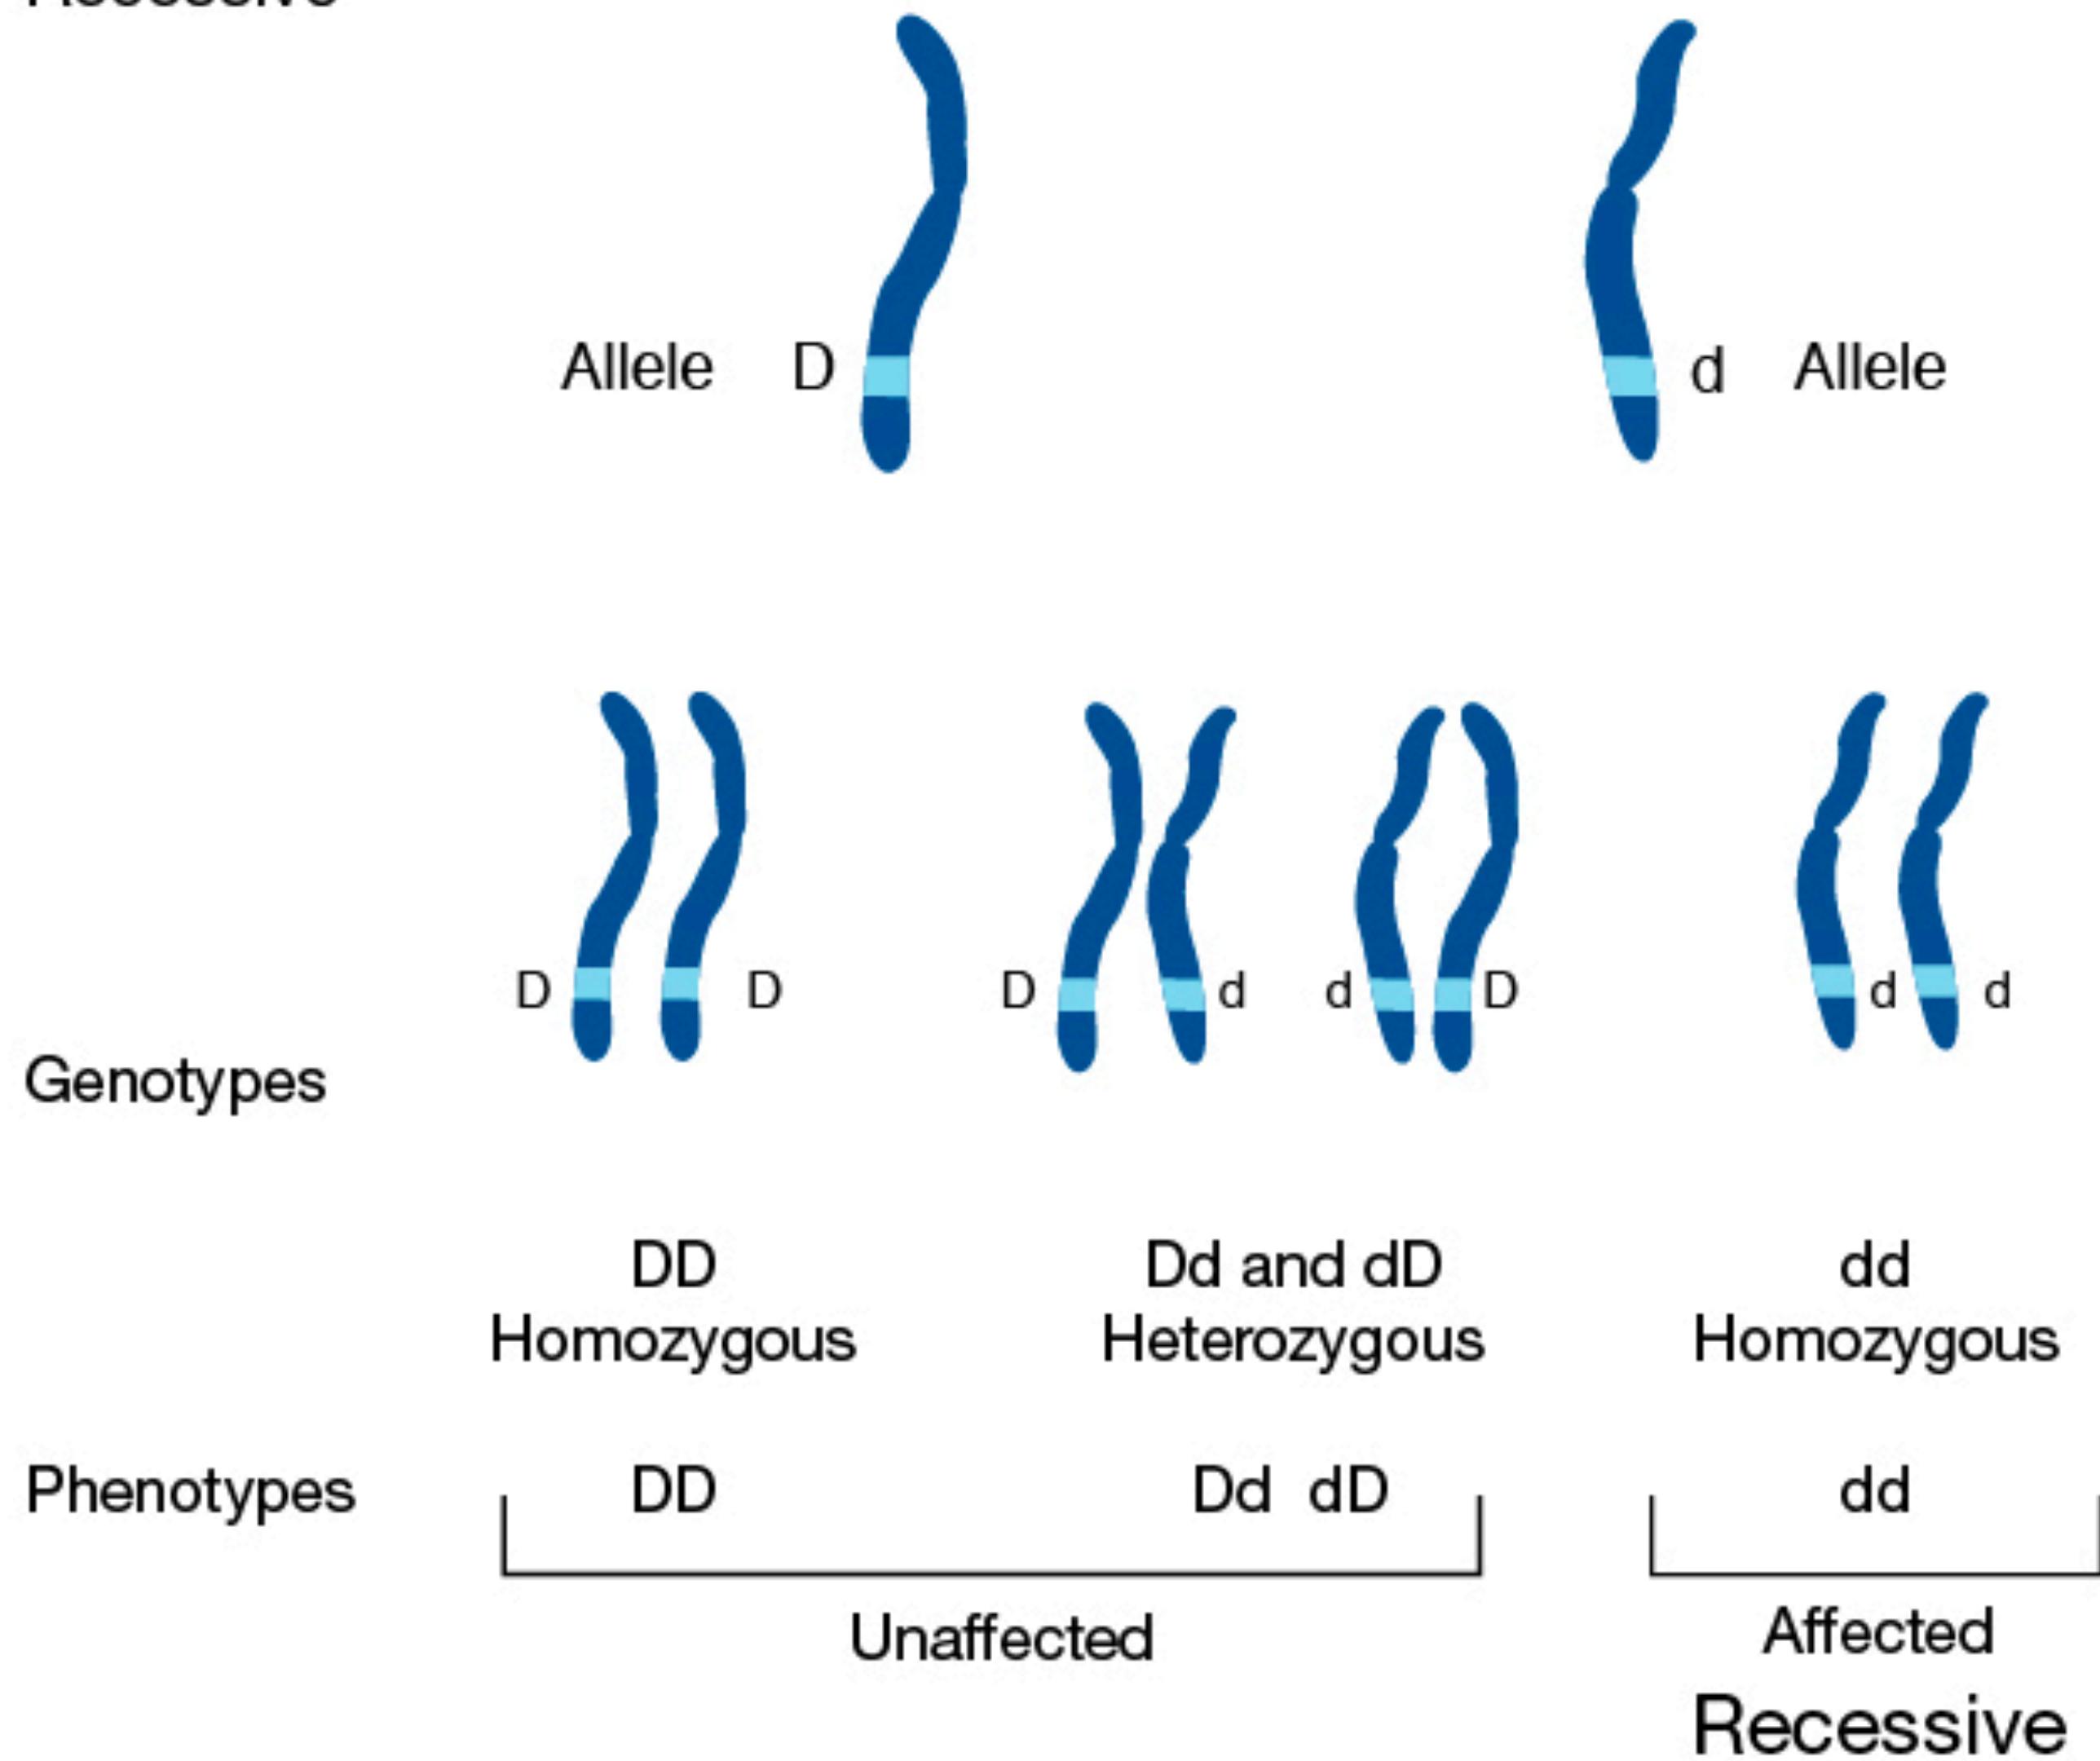

- Cystic Fibrosis
- Sickle-cell anemia
- Phenylketonuria
- Huntington's disease
- ...

Very high penetrance, monogenic

Huntington's Disease Dominant

OMIM® – Online Mendelian Inheritance in Man®

Welcome to OMIM®, Online Mendelian Inheritance in Man®. OMIM is a comprehensive, authoritative compendium of human genes and genetic phenotypes that is freely available and updated daily. The full-text, referenced overviews in OMIM contain information on all known mendelian disorders and over 16,000 genes. OMIM focuses on the relationship between phenotype and genotype. It is updated daily, and the entries contain copious links to other genetics resources.

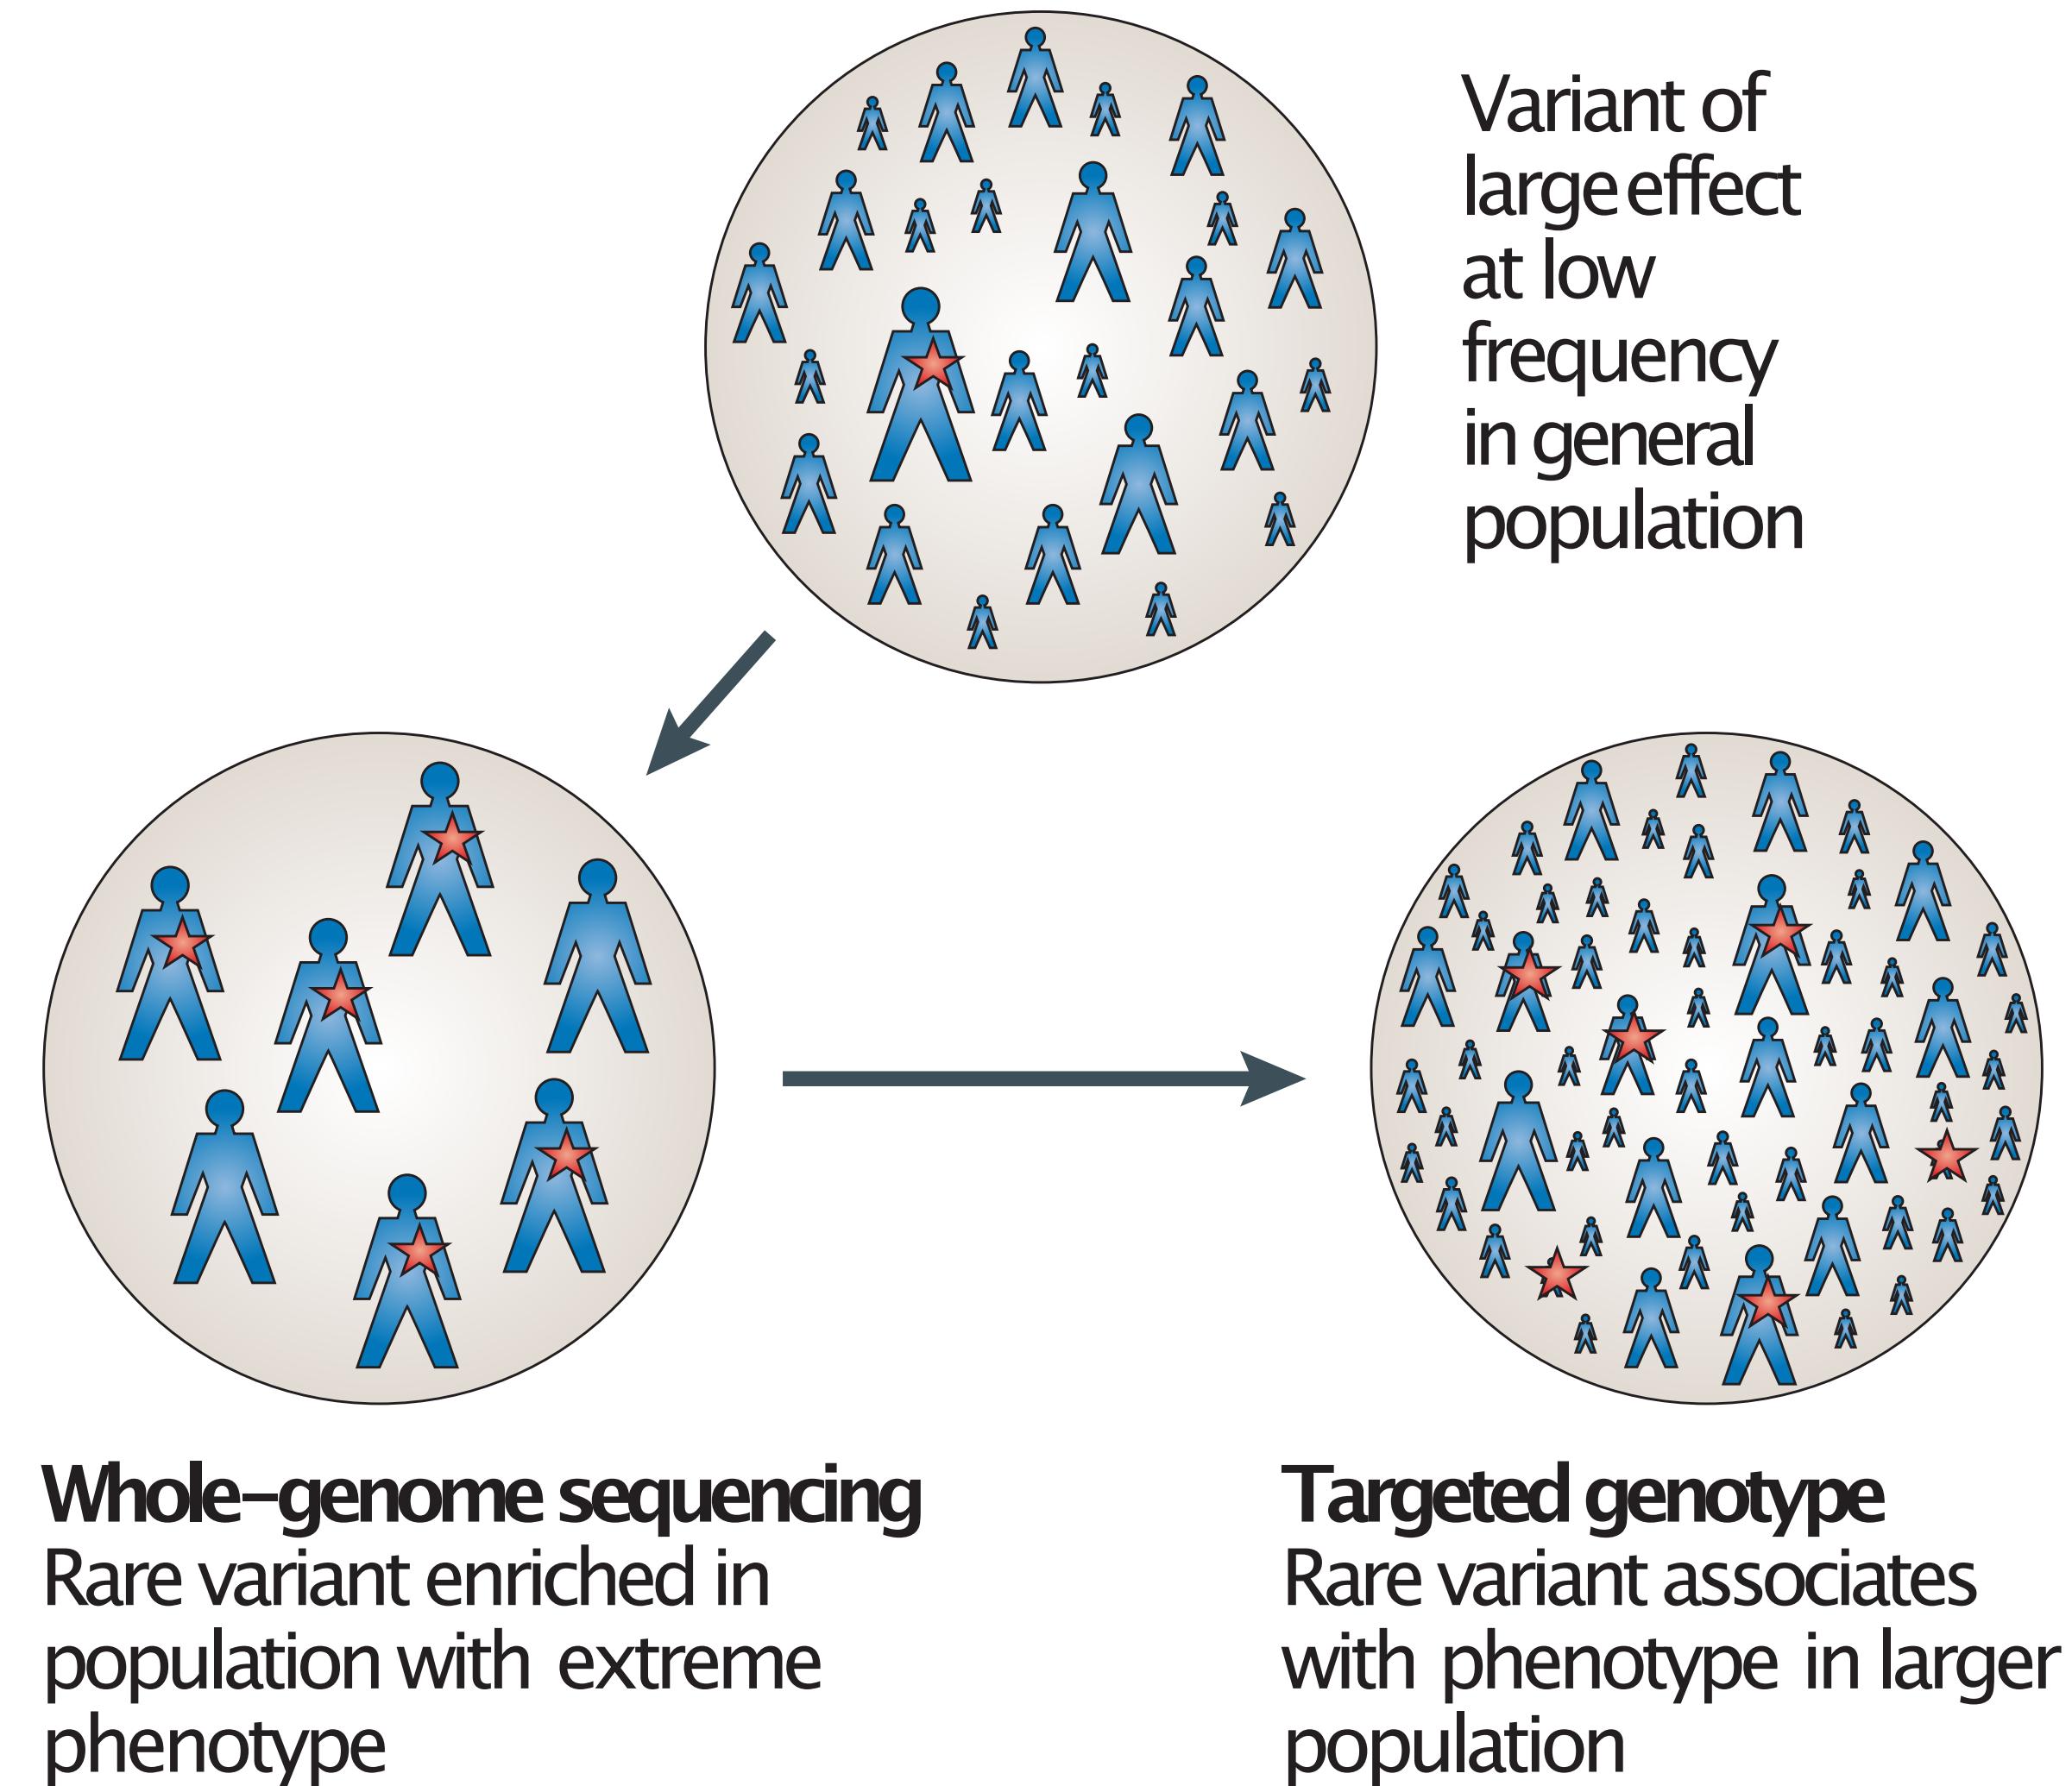

This database was initiated in the early 1960s by Dr. Victor A. McKusick as a catalog of mendelian traits and disorders, entitled Mendelian Inheritance in Man (MIM). Twelve book editions of MIM were published between 1966 and 1998. The online version, OMIM, was created in 1985 by a collaboration between the National Library of Medicine and the William H. Welch Medical Library at Johns Hopkins. It was made generally available on the internet starting in 1987. In 1995, OMIM was developed for the World Wide Web by NCBI, the National Center for Biotechnology Information.

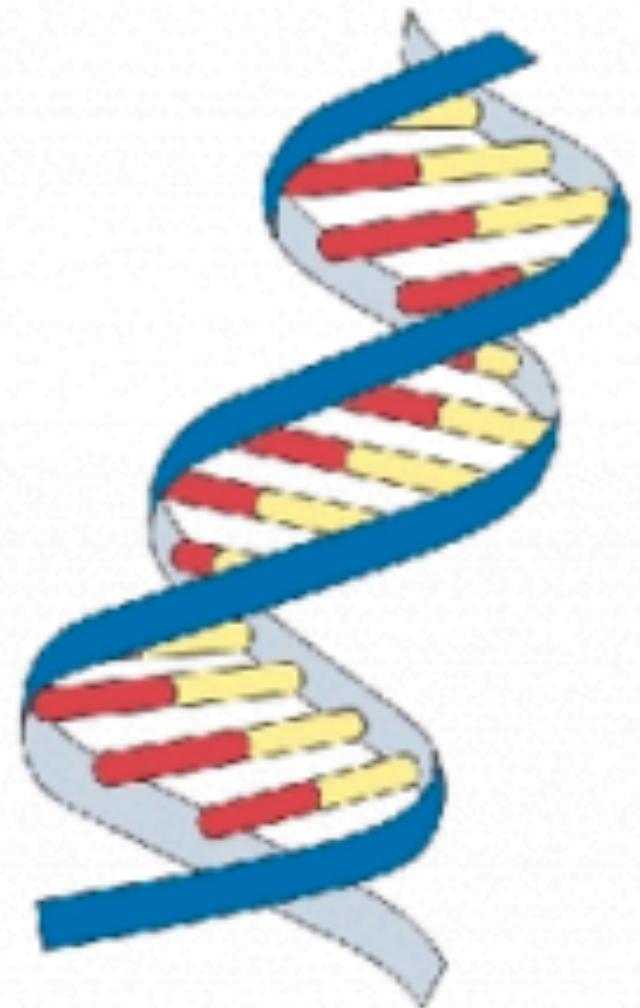

Targetted genotyping and sequencing

Population-level enrichment?

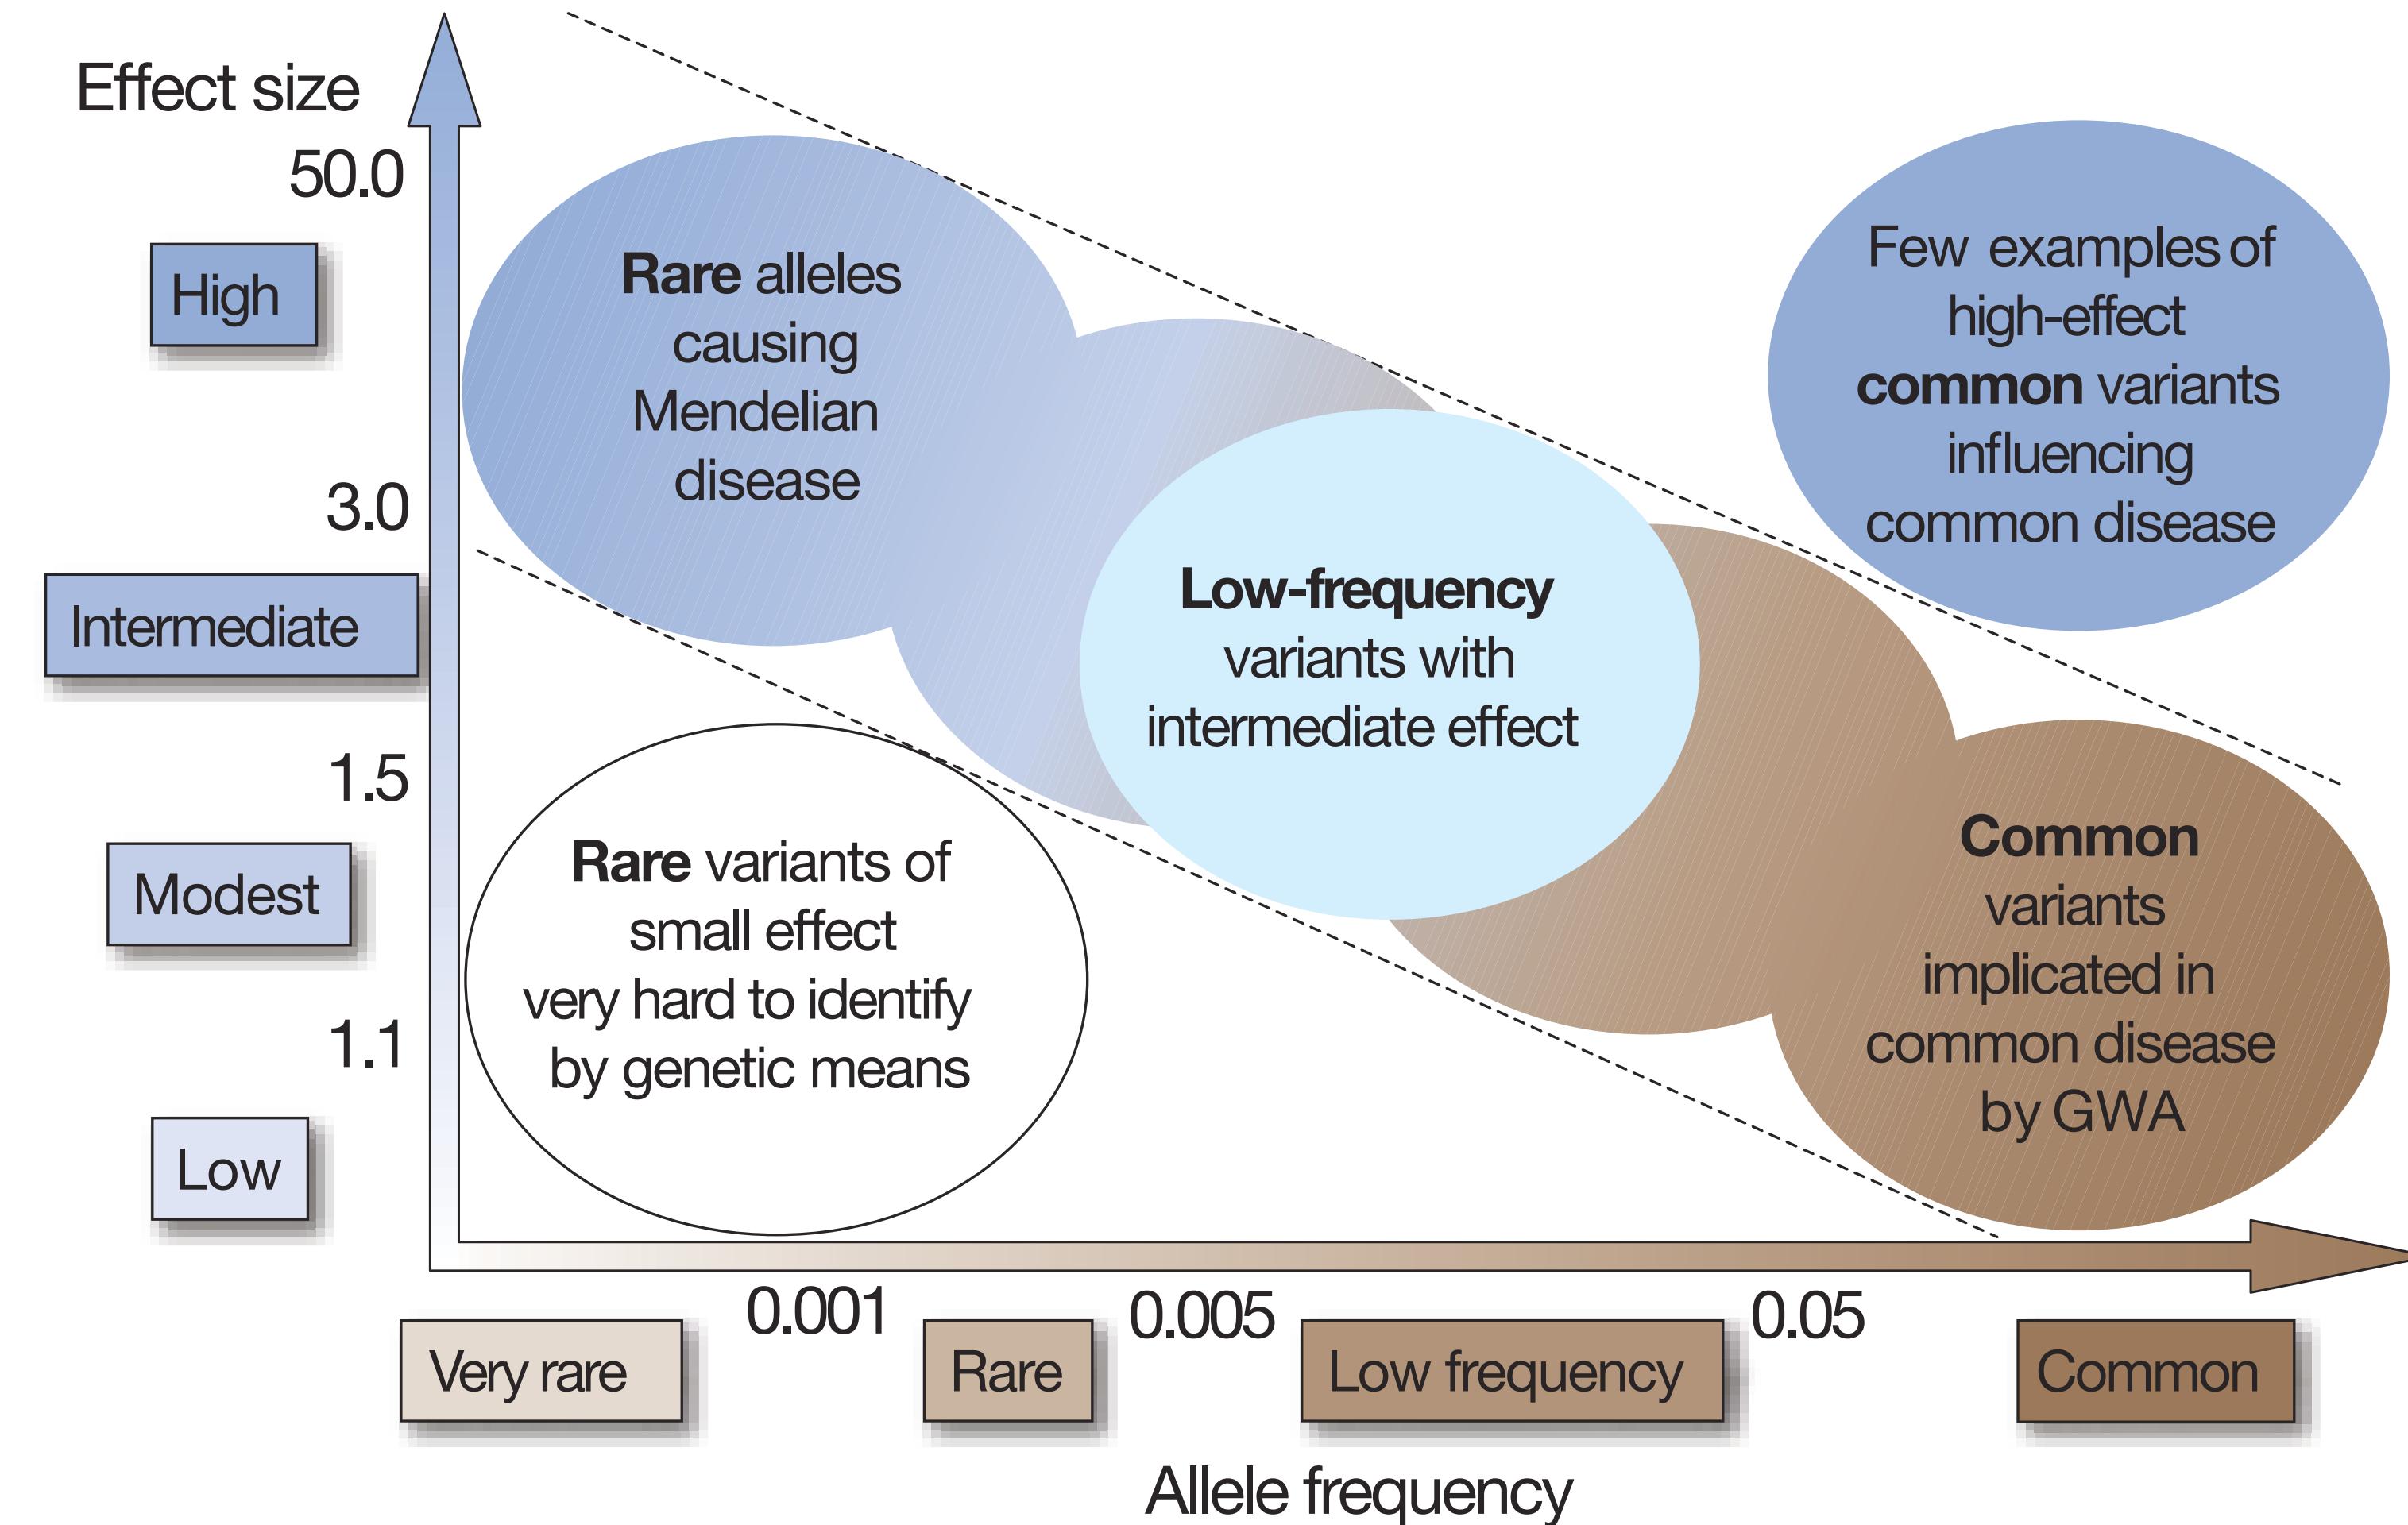

Can we identify variants associated with traits?

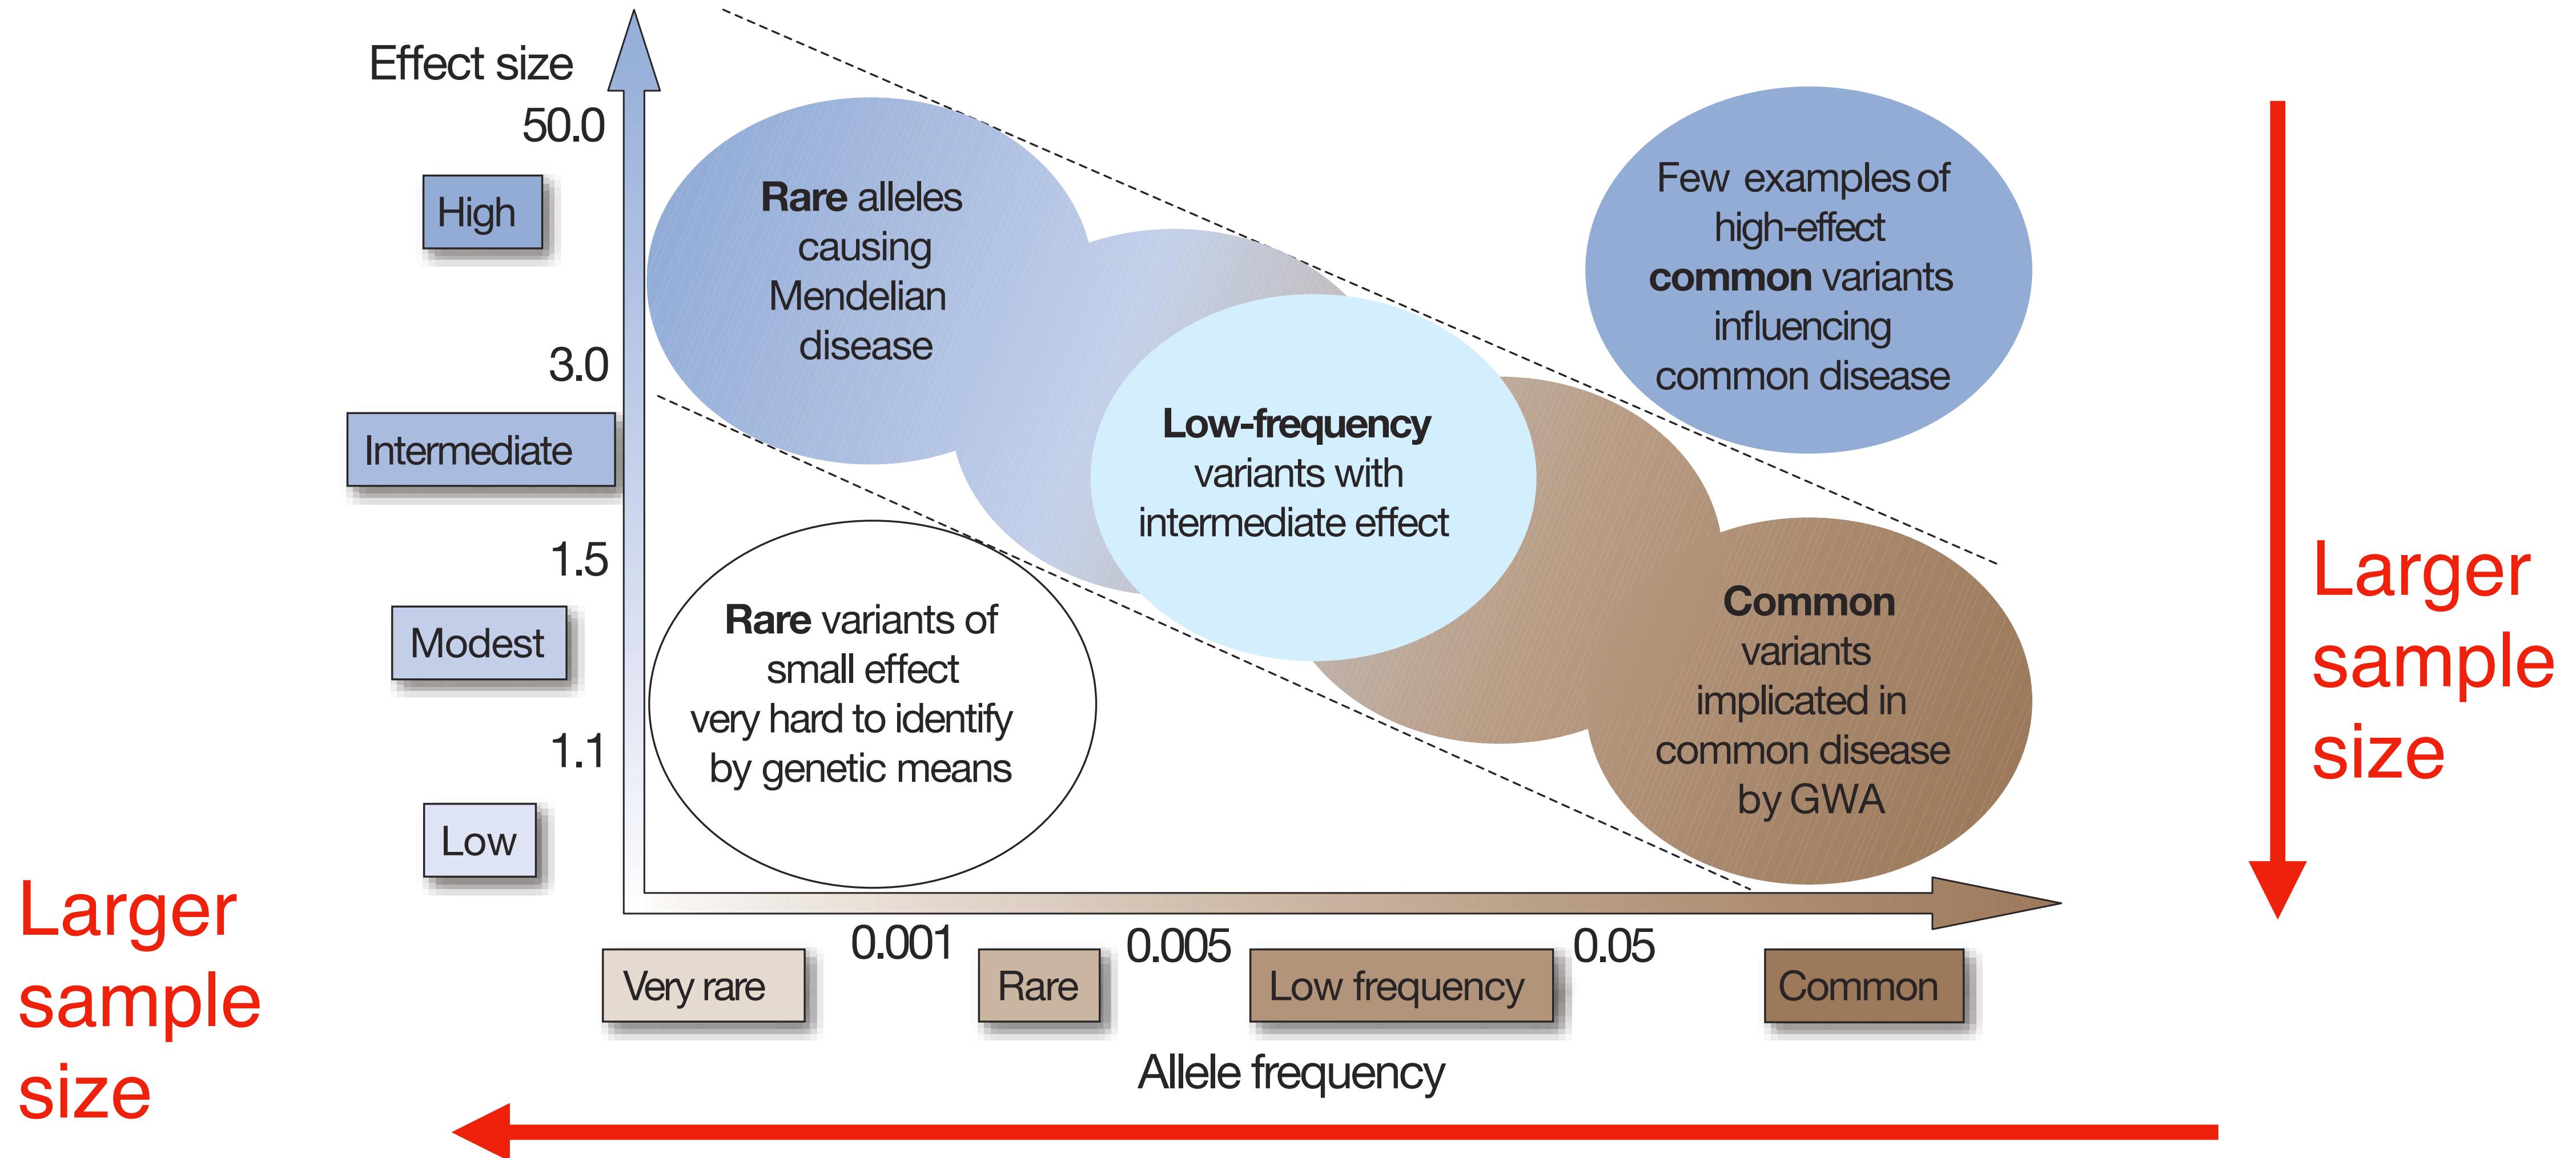

Genotypes are the genetic make-up of an individual.

Phenotypes are the physical traits and characteristics of an individual and are influenced by their genotype and the environment.

Will trait-associated variants emerge?

Will population-level genetic studies be of worth?

We need a large sample size!

Sample size matters (e.g., Schizophrenia GWAS)

1M "tagging" SNPs across the Human Genome

~ 1M independent loci (locations)

~ 5M variants

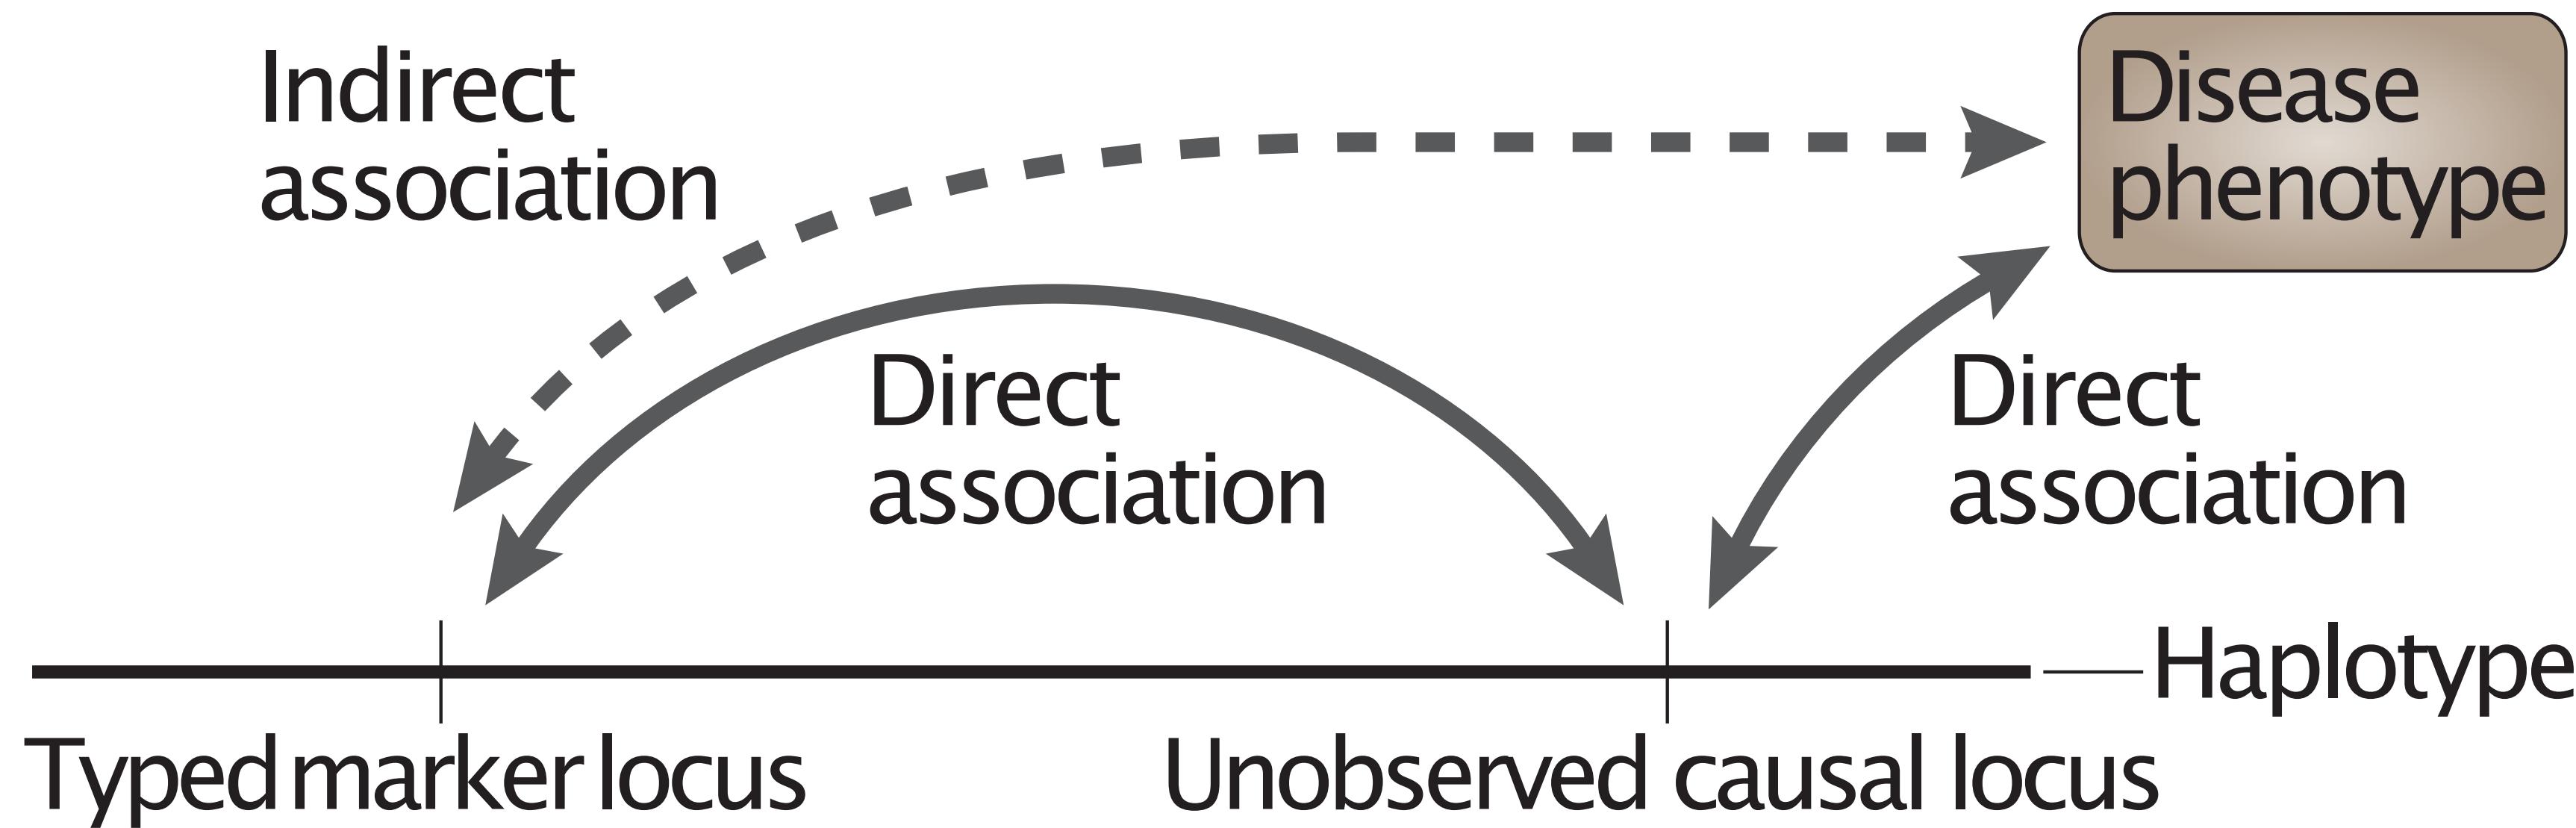

Genome-wide significance level

$$p_j < \frac{0.05}{\text{number of (independent) tests}} = \frac{0.05}{10^6} = 5 \times 10^{-8}$$

$$\text{FWER} = P \left(\cup_{j=1}^{10^6} \{p_j < 0.05/10^6\} \mid H_0 \right)$$

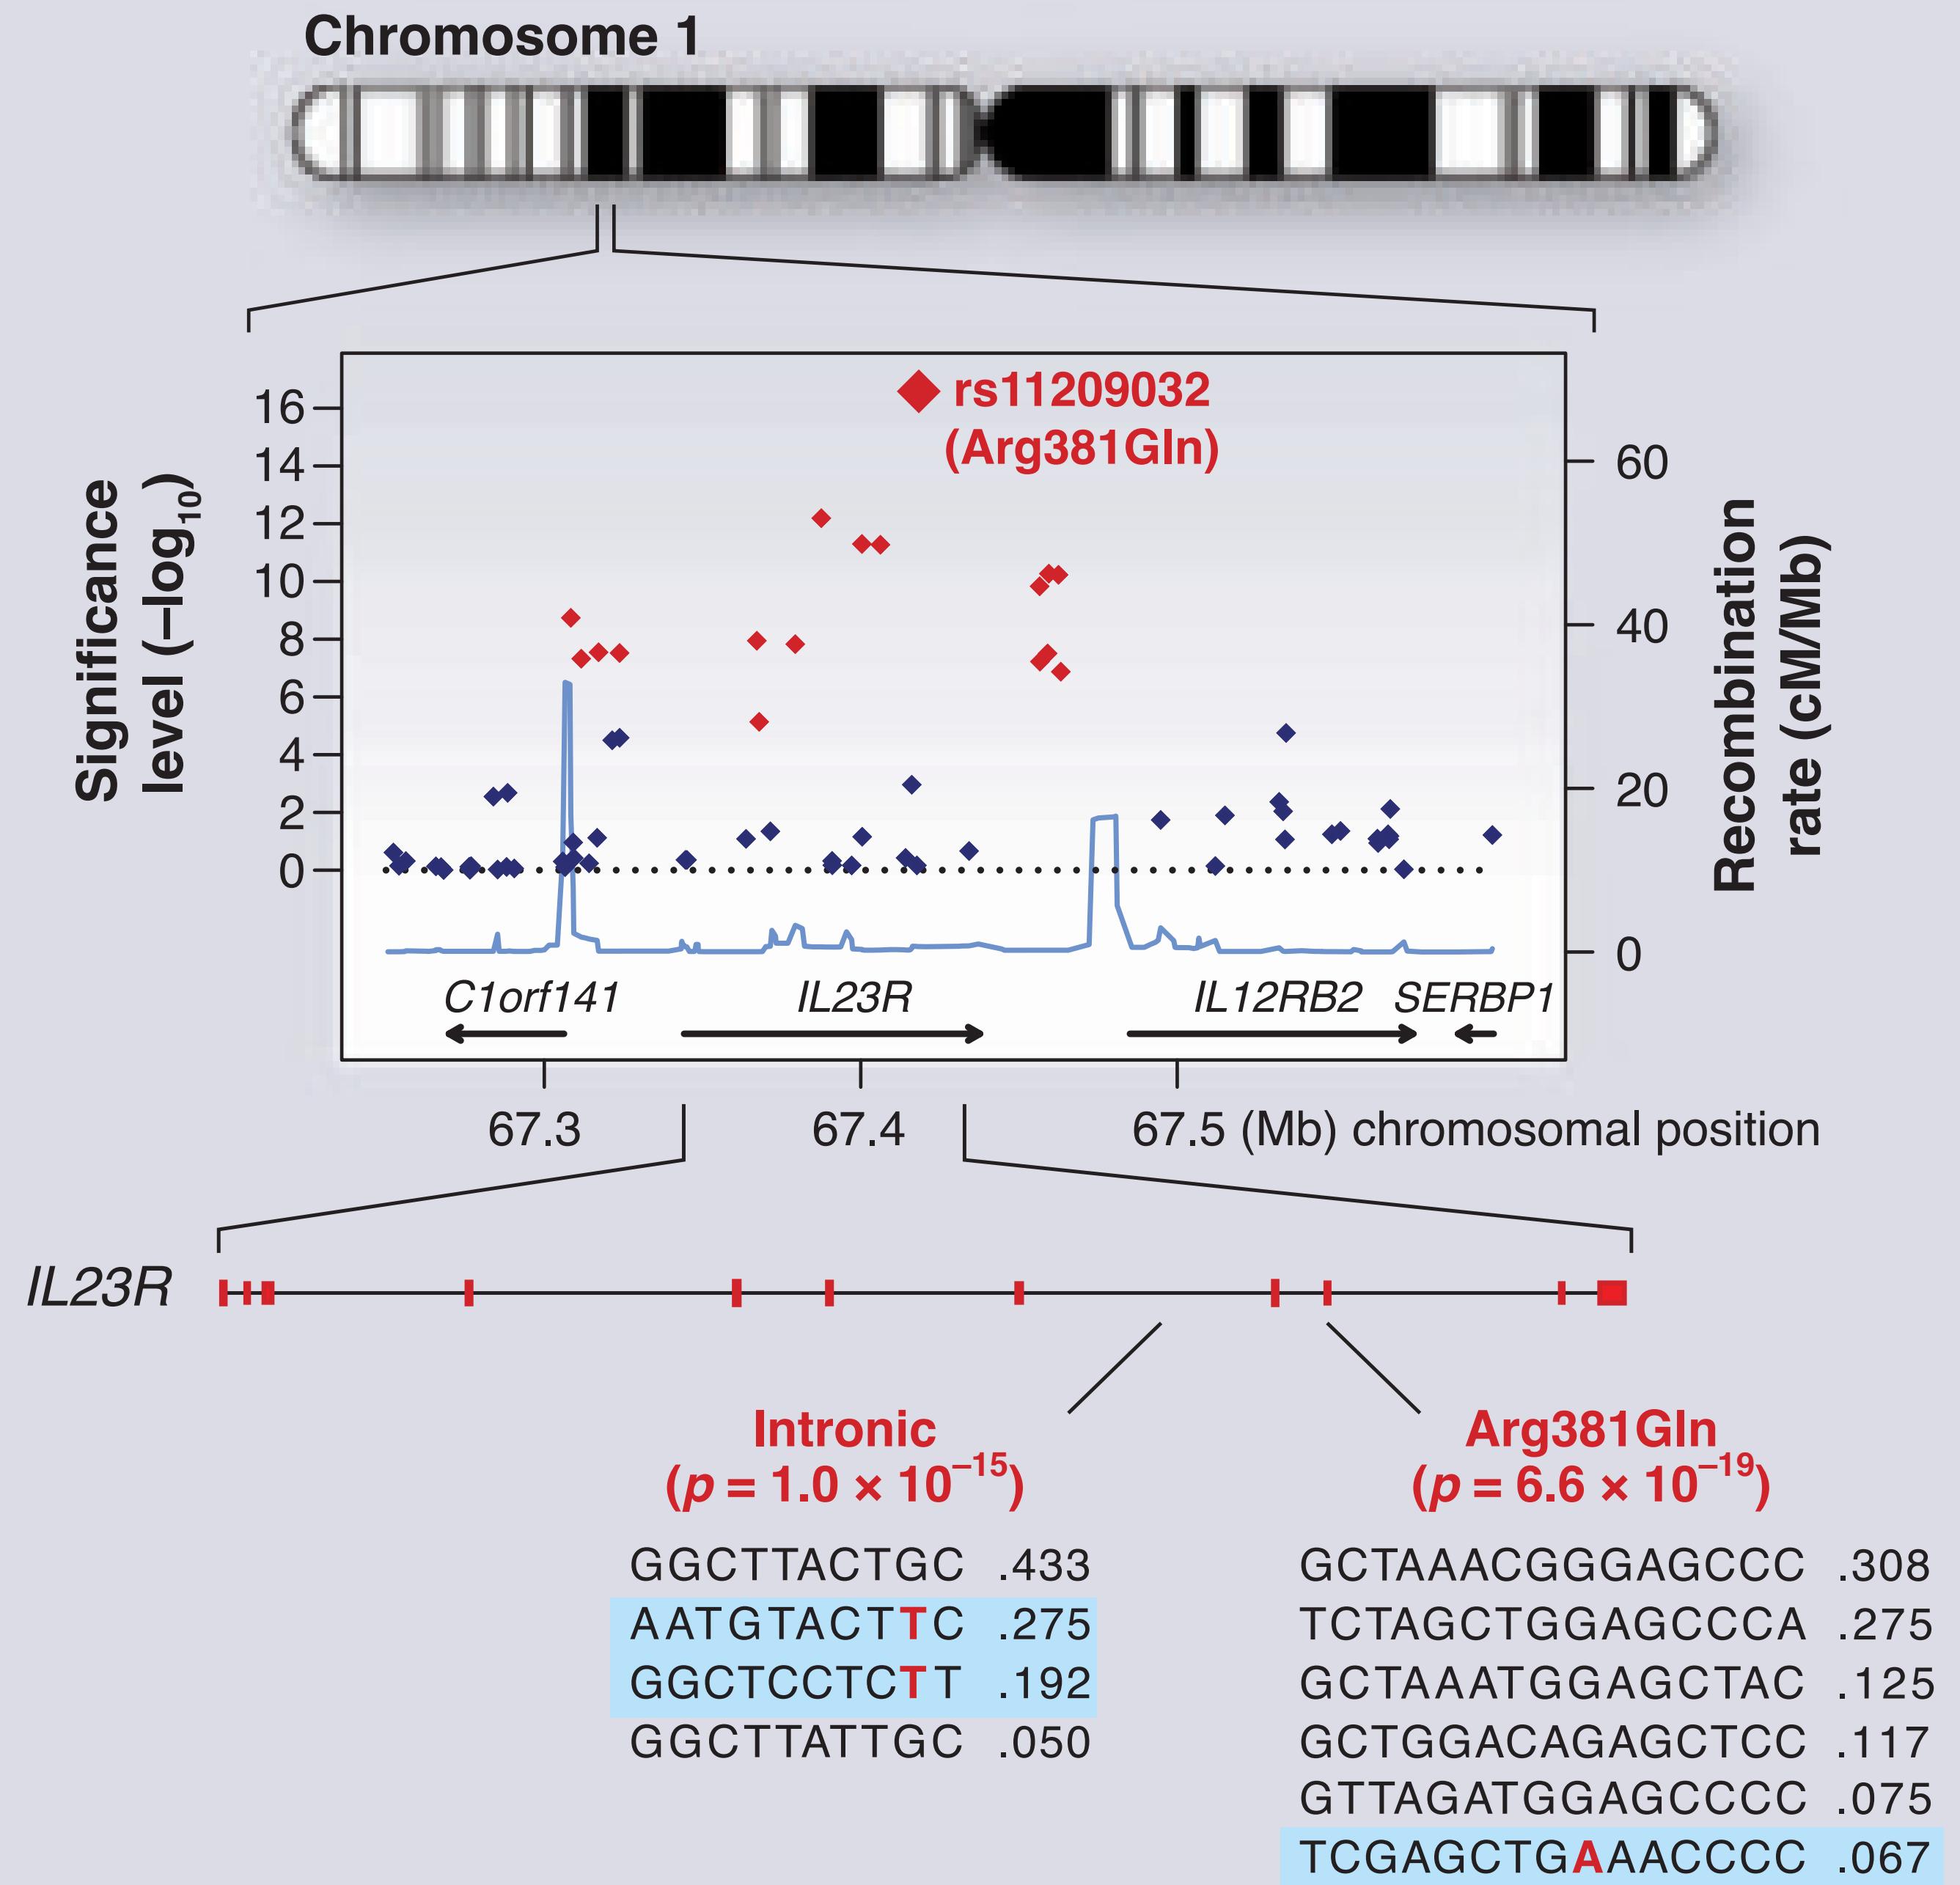

Union bound $< \sum_{j=1}^{10^6} P(p_j < 0.05/10^6 \mid H_0) = \sum_{j=1}^{10^6} \frac{0.05}{10^6} = 0.05$

Types of association (typed \approx tagging SNP)

GWAS only teach approximate locations of causal variants in the genome

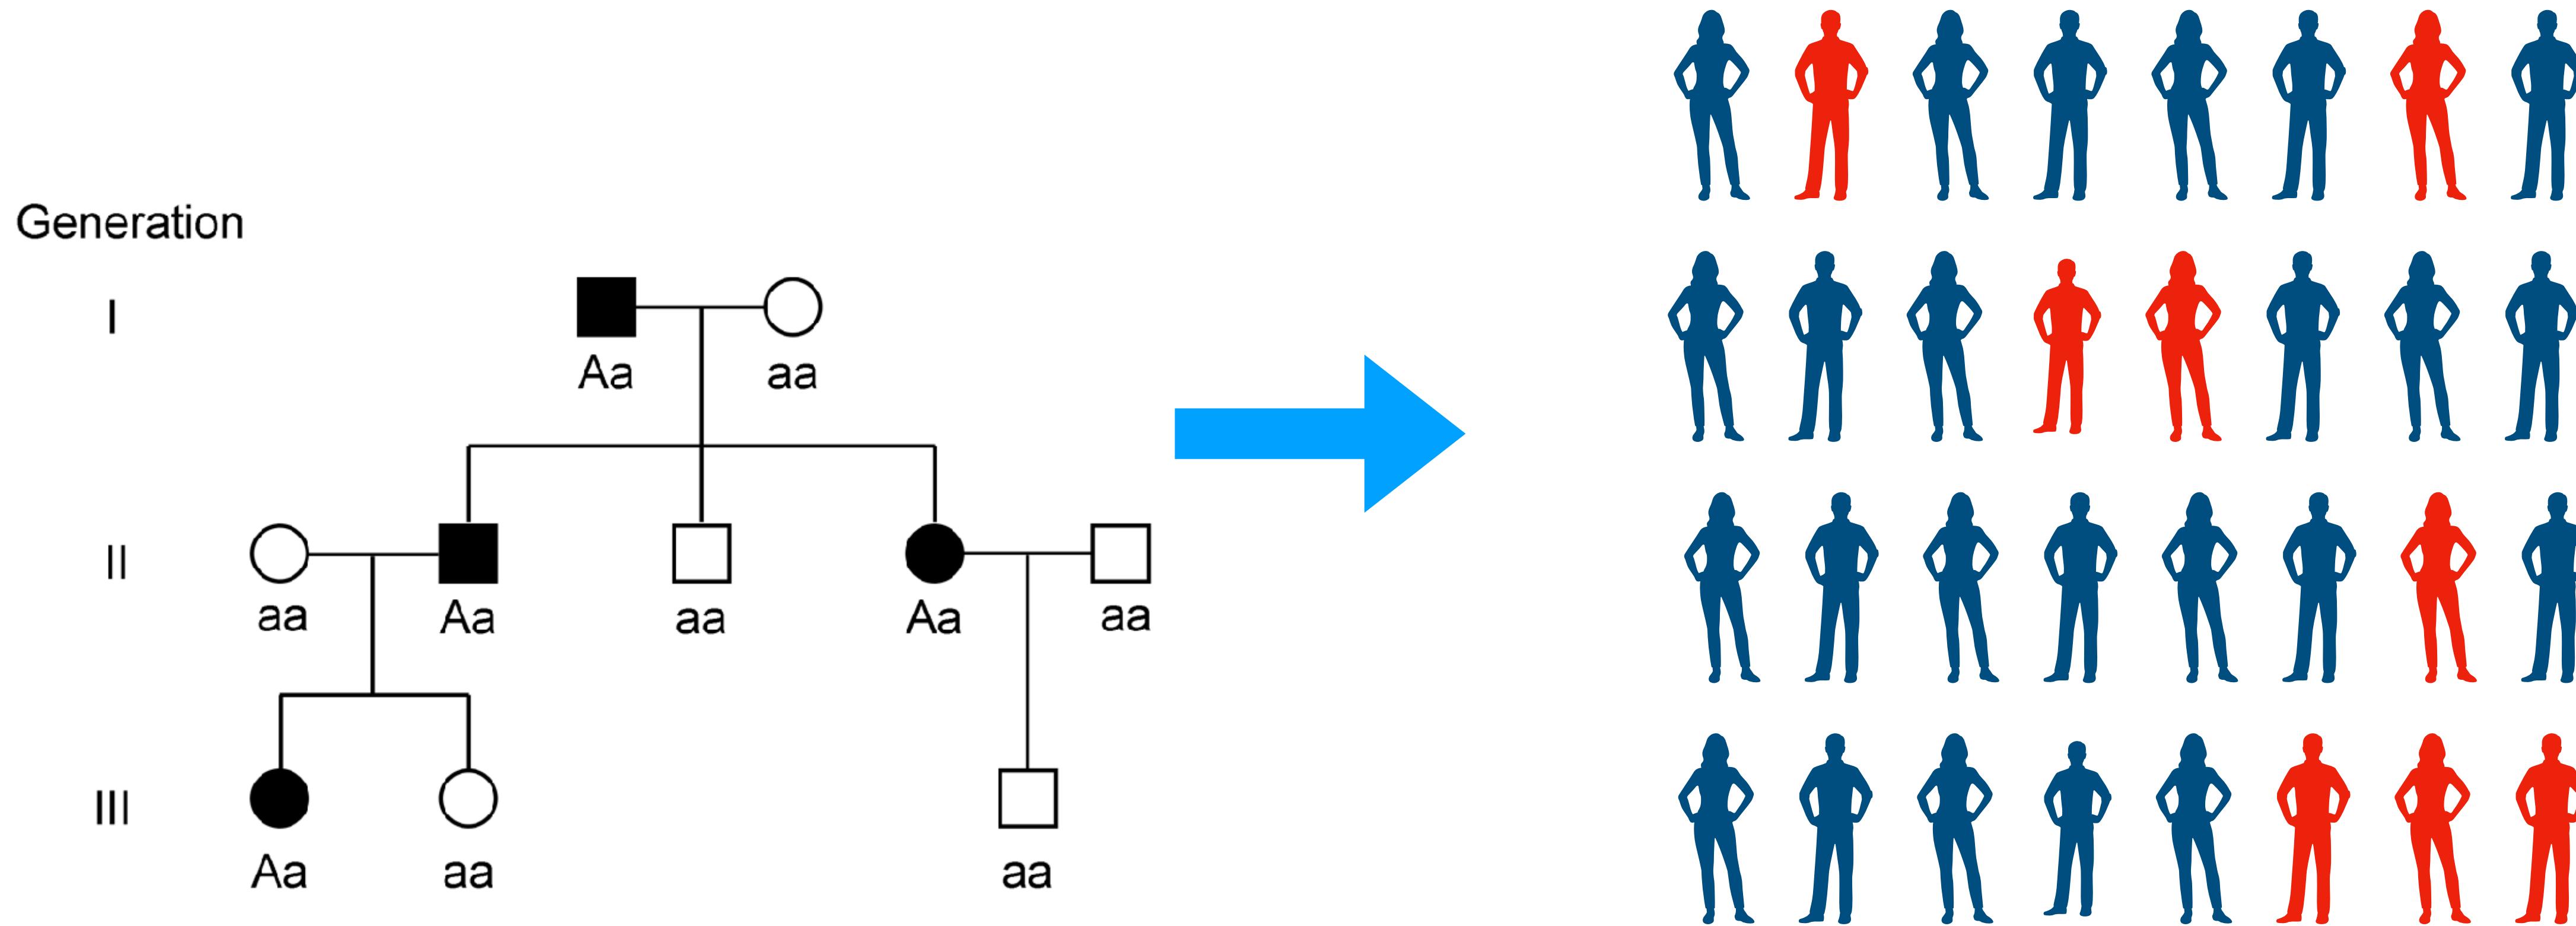

A close-up view of Genome-wide- significant loci

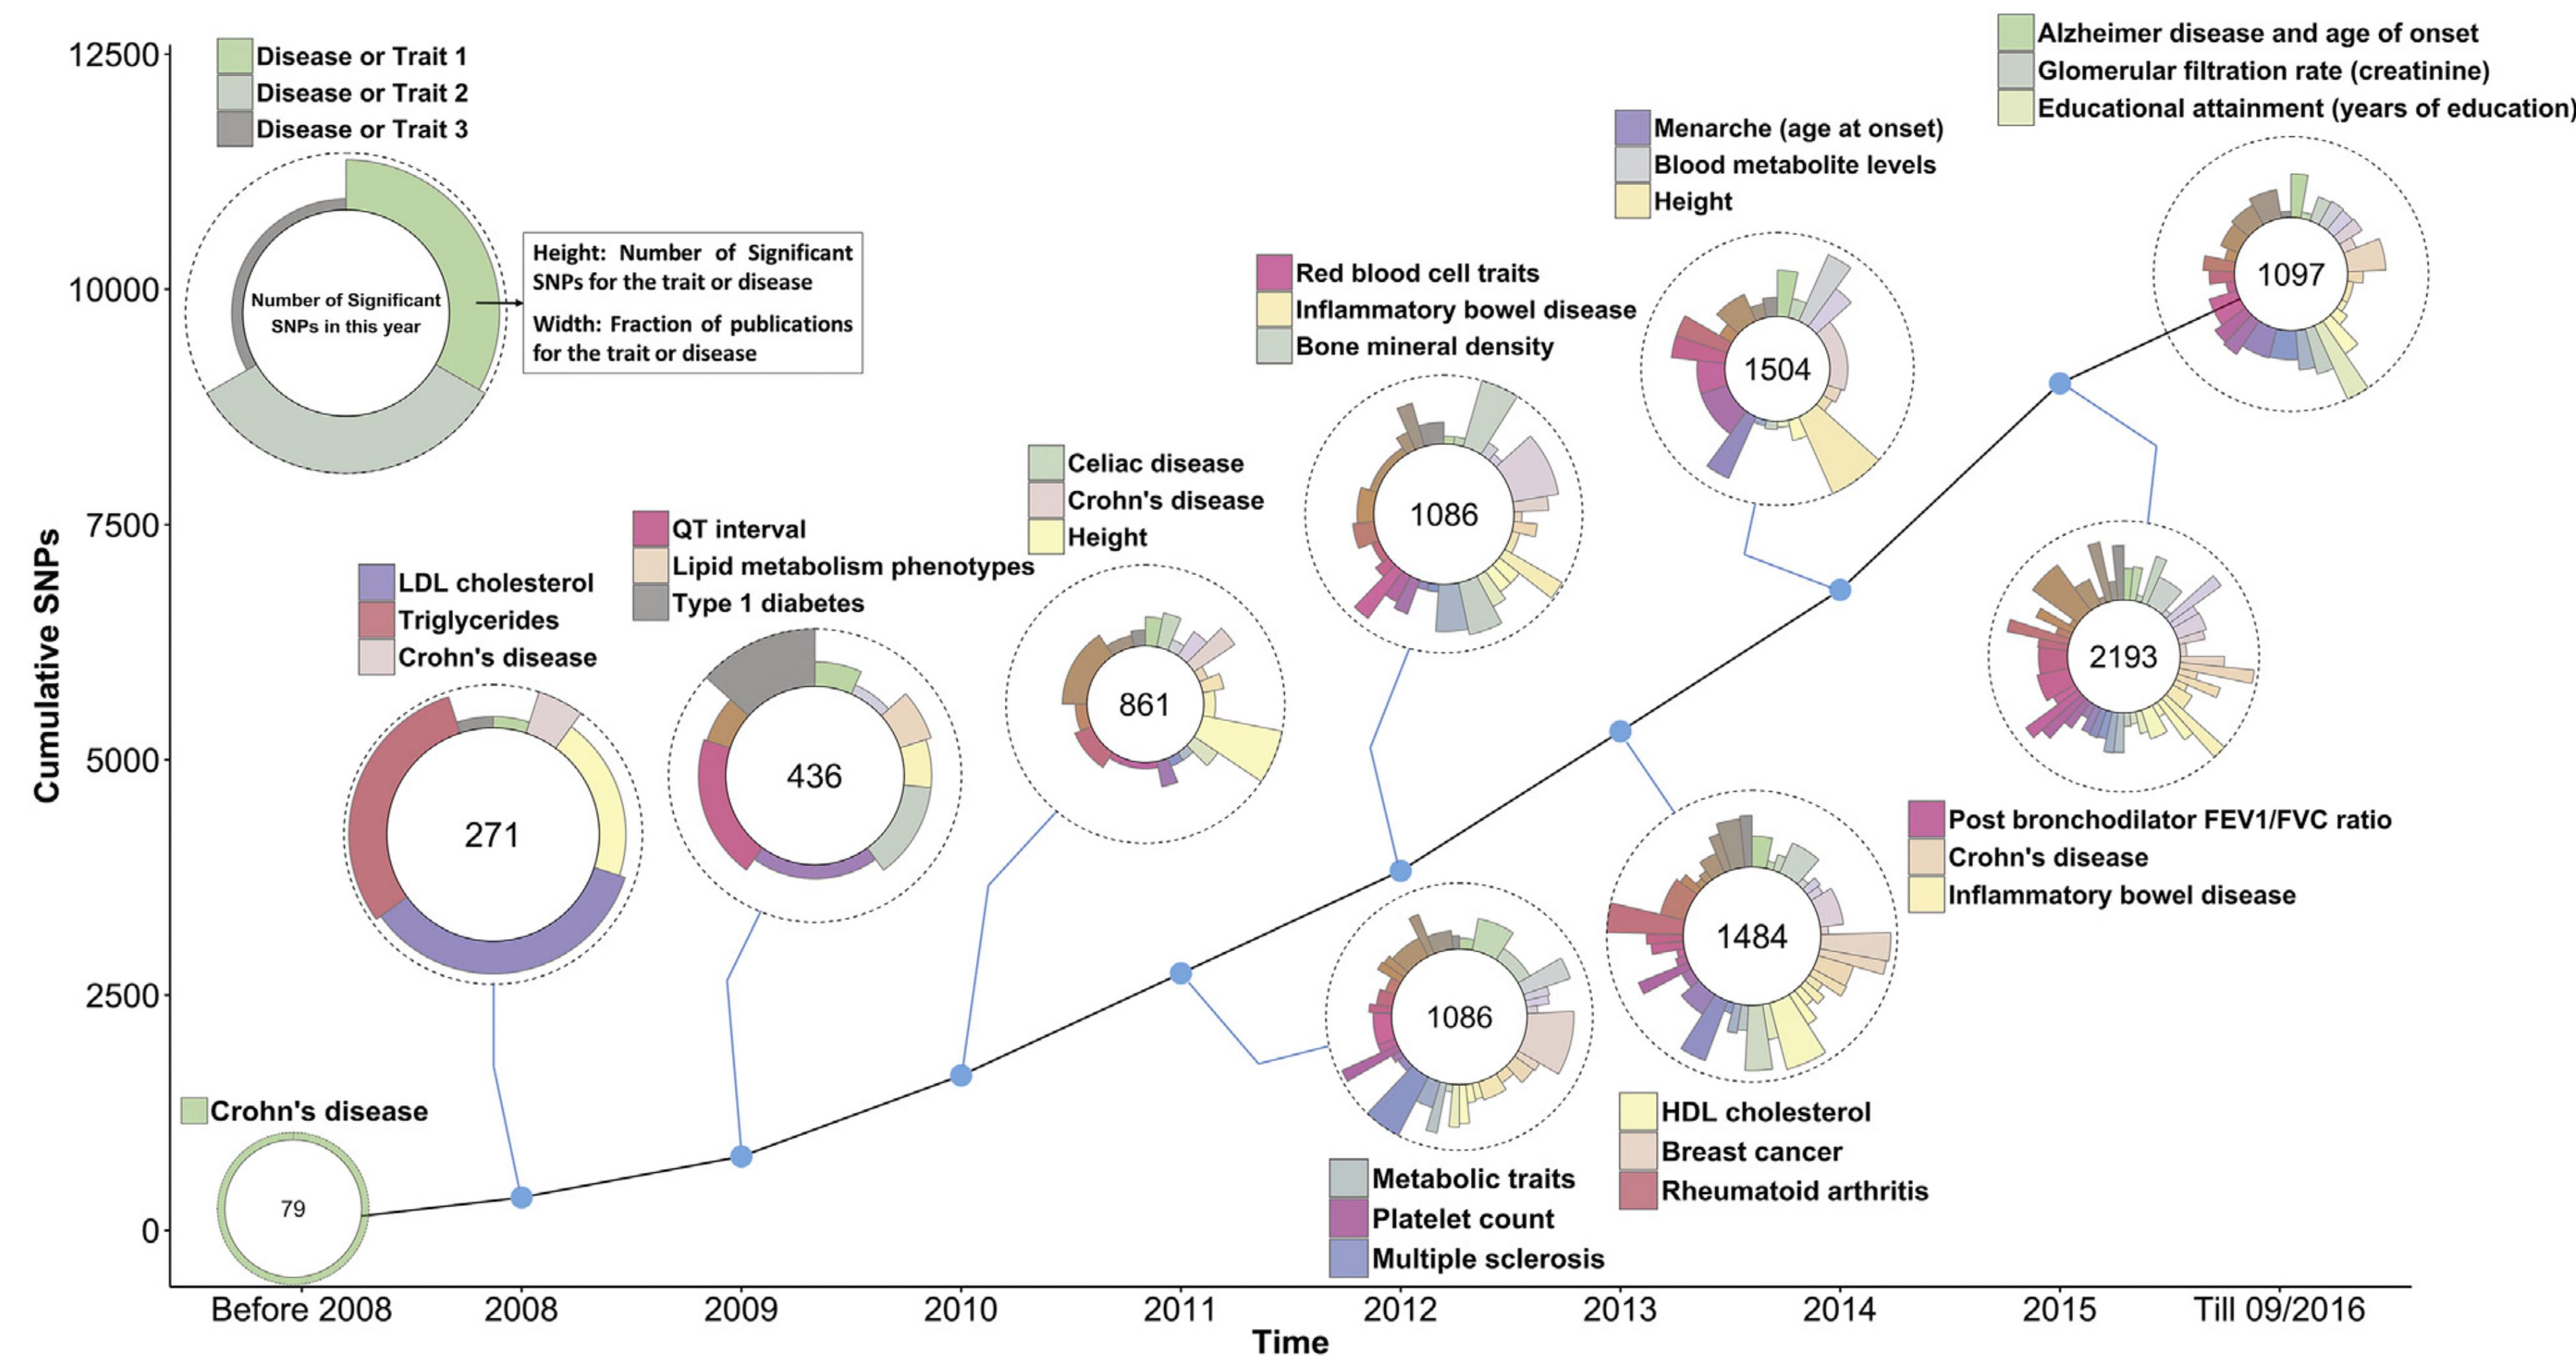

Summary for GWAS

- Massive multiple hypothesis testing associations between genetic variants and phenotypic changes
- Most studies focus on biallelic variants, coding them as {0, 1, 2}
- Most association statistics concern an additive effect of genotypes (linearity)
- Genetic variants closely located in the genome are strongly correlated with each other due to recombination
- Implicitly assume ~ 1M genetic variants (of tagging, or representative SNPs)
- GWAS only teach an approximate genomic locations associated with phenotypes

The success of GWAS changed the paradigm of human genetics studies

GWAS data/results increased rapidly

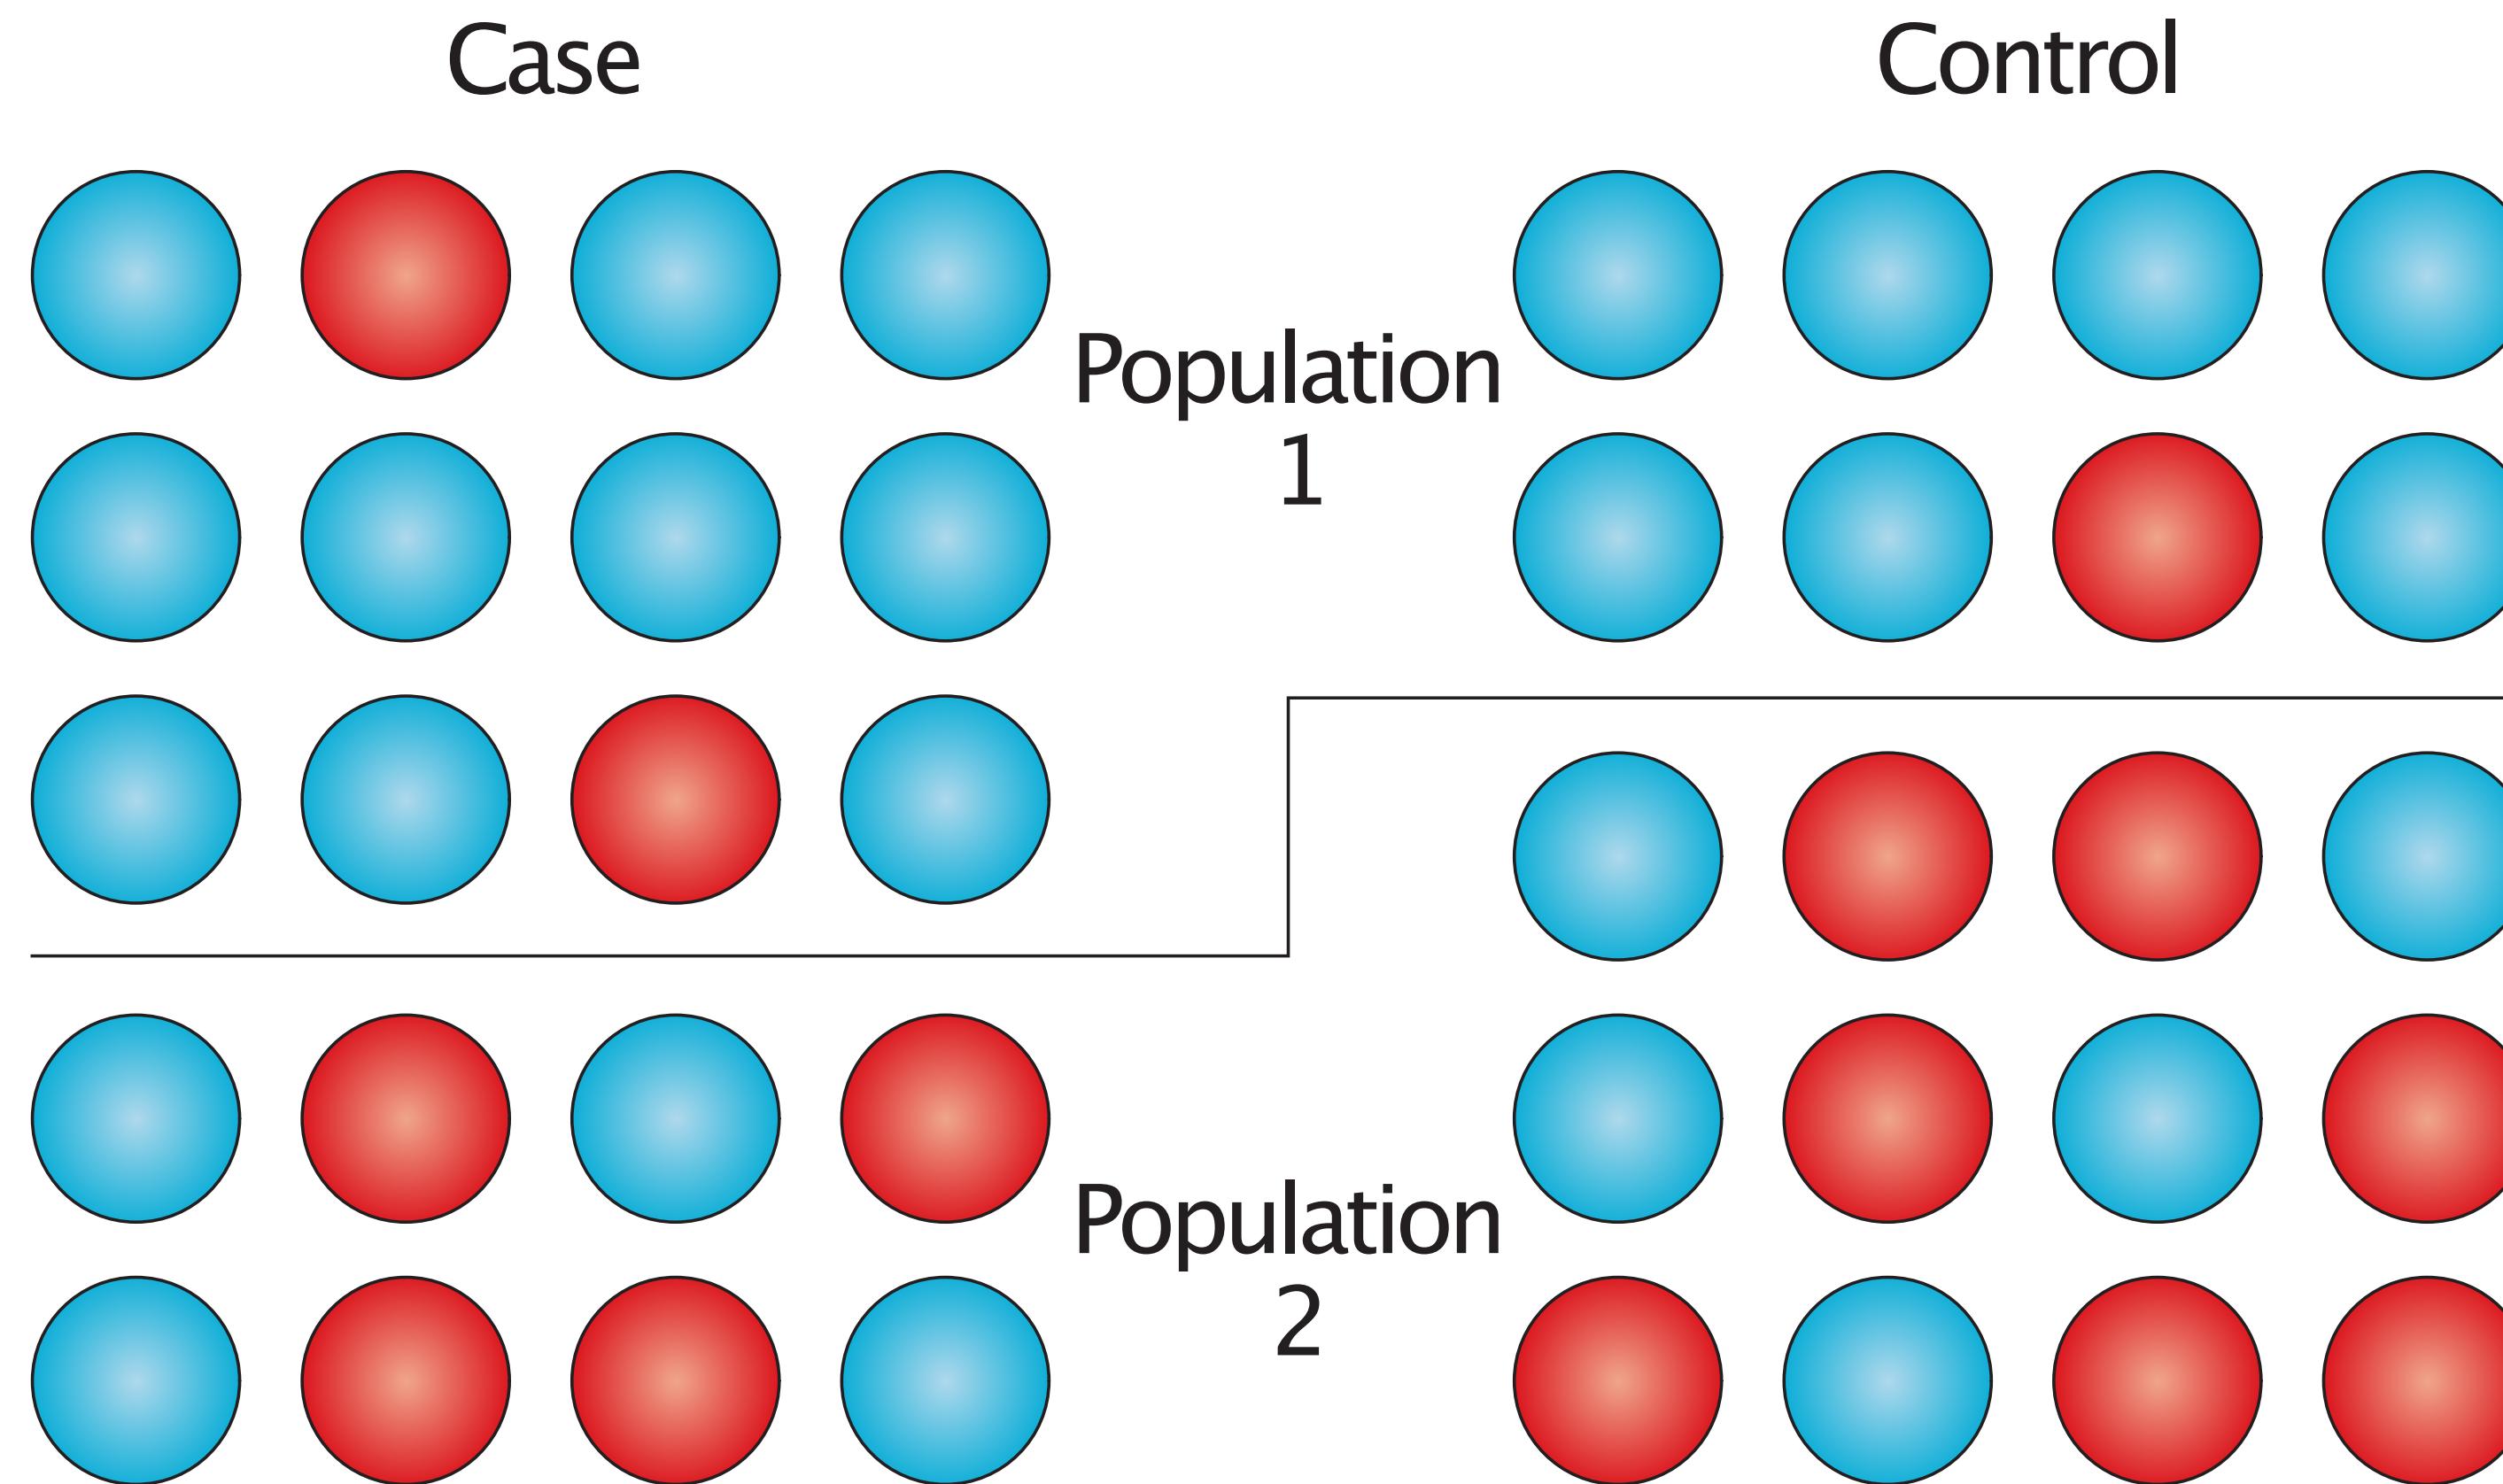

Big biobank-driven GWAS on prospective cohort

What if there were a hidden population structure?

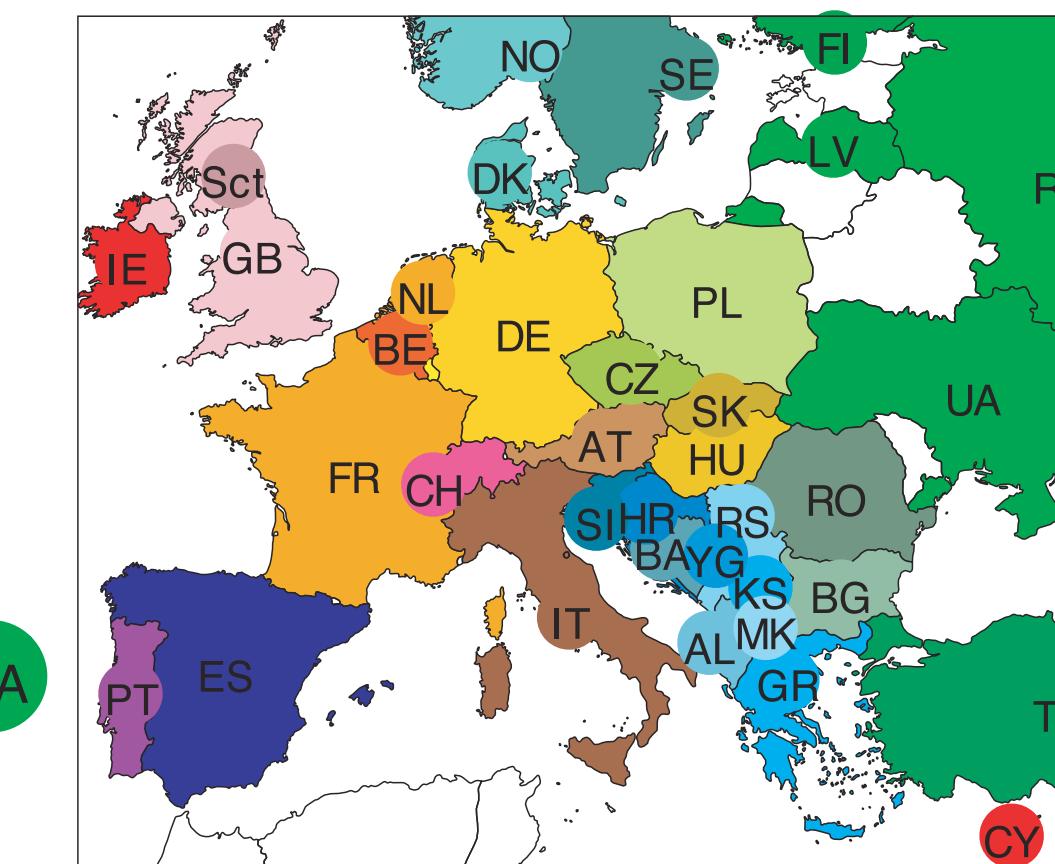

Hidden population structure in a causal graph

The human population as a result of the human migration history

Novembre et al.
Nature (2008)

Much of human genetics problems centre on two covariance matrices

For a standardized $n \times p$ genotype matrix X (n : #individuals, p : #SNPs),

1. Genetic relatedness matrix (GRM)

individual by individual, $n \times n$ matrix

$$K \approx XX^\top/n$$

The matrix K captures population structure/correlation across different individuals.

- ▶ Kinship matrix; population admixture
- ▶ Human migration history

2. Linkage disequilibrium (LD)

SNP by SNP, $p \times p$ matrix

$$R \approx X^\top X/n$$

The matrix R captures localized correlation patterns along the genomic axis within a chromosome.

- ▶ LD matrix
- ▶ The results of many, many recombination events

1000 Genomes project data

1KG contains whole genome sequencing data of 2,490 individuals sampled from 26 groups based on the origins and geographical locations (as of 2013 phase3).

See Online Methods for definitions of notations.

Using a linear mixed effect model

Population structures and polygenicity may inflate GWAS stats

Unmeasured confounding

Simply there are so many causal variants

(digression) Useful facts on multivariate Gaussian distribution - 1

If we have \mathbf{y}

$$\mathbf{y} \sim \mathcal{N}(\mu, \Sigma)$$

then

$$\mathbb{E}[U^\top \mathbf{y}] = U^\top \mu, \quad \mathbb{V}[U^\top \mathbf{y}] = U^\top \Sigma U$$

and (affine transformation)

$$U^\top \mathbf{y} \sim \mathcal{N}(U^\top \mu, U^\top \Sigma U)$$

(digression) Useful facts on multivariate Gaussian distribution - 2

If we have two Gaussian random vectors, $\mathbf{y} \sim \mathcal{N}(\mu + \mathbf{u}, \Sigma_y)$ and $\mathbf{u} \sim \mathcal{N}(\mathbf{u}|0, \Sigma_u)$

Bayesian integration:

$$\int \mathcal{N}(\mathbf{y}|\mu + \mathbf{u}, \Sigma_y) \mathcal{N}(\mathbf{u}|0, \Sigma_u) d\mathbf{u} = \mathcal{N}(\mathbf{y}|\mu, \Sigma_y + \Sigma_u)$$

A key idea in the proof:

$$\left[\Sigma_y^{-1} - \Sigma_y^{-1} \left(\Sigma_y^{-1} + \Sigma_u^{-1} \right)^{-1} \Sigma_y^{-1} \right]^{-1} = \Sigma_y + \Sigma_u$$

by Woodbury identity.

A linear model with population-driven random effects

A linear regression model:

$$\mathbf{y} = \mathbf{x}_j \beta_j + \epsilon$$

a fixed genetic effect

What are we missing? Can we assume
homo-scedasticity, i.e.,

$$\epsilon \stackrel{?}{\sim} \mathcal{N}(\mathbf{0}, \sigma^2 I)$$

A linear model with population-driven random effects

A linear regression model:

$$\mathbf{y} = \mathbf{x}_j \beta_j + \epsilon$$

a fixed genetic effect

What are we missing? Can we assume homo-scedasticity, i.e.,

$$\epsilon \stackrel{?}{\sim} \mathcal{N}(\mathbf{0}, \sigma^2 I)$$

A linear model with a random effect:

$$\mathbf{y} = \mathbf{x}_j \beta_j + \mathbf{u} + \epsilon$$

fixed random effect

Note: There is no specific parameterization for this $n \times 1$ random vector \mathbf{u} . Now, we assume:

$$\epsilon \sim \mathcal{N}(\mathbf{0}, \sigma^2 I)$$

A linear model with population-driven random effects - 2

We want to capture unwanted population, cohort-specific random effects by $n \times 1$ vector \mathbf{u} and **remove** since our **goal** is to estimate the fixed genetic effect of a particular variant j .

$$\mathbf{y} = \mathbf{x}_j \beta_j + \underset{\text{goal}}{\mathbf{u}} + \epsilon$$

A linear model with population-driven random effects - 2

We want to capture unwanted population, cohort-specific random effects by $n \times 1$ vector \mathbf{u} and **remove** since our **goal** is to estimate the fixed genetic effect of a particular variant j .

$$\mathbf{y} = \mathbf{x}_j \beta_j + \underset{\text{goal}}{\mathbf{u}} + \epsilon$$

1. Note that \mathbf{u} shouldn't be tied to a particular variant (by definition)

A linear model with population-driven random effects - 2

We want to capture unwanted population, cohort-specific random effects by $n \times 1$ vector \mathbf{u} and **remove** since our **goal** is to estimate the fixed genetic effect of a particular variant j .

$$\mathbf{y} = \mathbf{x}_j \beta_j + \underset{\text{goal}}{\mathbf{u}} + \epsilon$$

1. Note that \mathbf{u} shouldn't be tied to a particular variant (by definition)
2. Also, the covariation of \mathbf{u} is primarily driven by relatedness among individuals, not the variants.

$$\mathbf{u} \sim \mathcal{N}(0, \tau^2 K), \quad K \approx \frac{1}{n} \mathbf{X} \mathbf{X}^\top$$

A linear mixed effect model (LMM) to test associations while adjusting population structure

We can define a hierarchical model:

$$\mathbf{y}|X, \beta, \mathbf{u}, \sigma \sim \mathcal{N}(X\beta + \mathbf{u}, \sigma^2 I) \quad (1)$$

$$\mathbf{u}|\tau, K \sim \mathcal{N}(\mathbf{0}, \tau^2 K) \quad (2)$$

If we integrate out \mathbf{u} ,

$$\mathbf{y}|X, \beta \sim \mathcal{N}\left(\mathbf{y} \mid X\beta, \underbrace{\tau^2 K}_{\text{genetic-relatedness matrix}} + \underbrace{\sigma^2 I}_{\text{irreducible}} \right)$$

Why using LMM instead of regressing out confounding factors?

- ▶ It is hard to distinguish between causative vs. confounding effects

Why using LMM instead of regressing out confounding factors?

- ▶ It is hard to distinguish between causative vs. confounding effects
- ▶ Cumbersome computation required for matrix factorization or other latent variable modelling on a large genotype matrix

Why using LMM instead of regressing out confounding factors?

- ▶ It is hard to distinguish between causative vs. confounding effects
- ▶ Cumbersome computation required for matrix factorization or other latent variable modelling on a large genotype matrix
- ▶ We many not have a large matrix to learn about non-genetic confounders...

Why using LMM instead of regressing out confounding factors?

- ▶ It is hard to distinguish between causative vs. confounding effects
- ▶ Cumbersome computation required for matrix factorization or other latent variable modelling on a large genotype matrix
- ▶ We may not have a large matrix to learn about non-genetic confounders...
- ▶ One LMM estimation can substitute multiple matrix factorization steps

Why using LMM instead of regressing out confounding factors?

- ▶ It is hard to distinguish between causative vs. confounding effects
- ▶ Cumbersome computation required for matrix factorization or other latent variable modelling on a large genotype matrix
- ▶ We may not have a large matrix to learn about non-genetic confounders...
- ▶ One LMM estimation can substitute multiple matrix factorization steps
- ▶ We may have a good idea about relationships induced by random effects!

FaST Linear Mixed Model (Lippert *et al.* 2011)

We can resolve maximum likelihood estimate of the parameters, β, τ, σ ,

$$\max \log \mathcal{N}(\mathbf{y} | X\beta, \sigma_2 (\delta K + I))$$

where $\tau^2 = \delta\sigma^2$.

Lippert, Listgarten, .. , Heckerman, *Nature Methods* (2011)

FaST Linear Mixed Model (Lippert *et al.* 2011)

We can resolve maximum likelihood estimate of the parameters, β, τ, σ ,

$$\max \log \mathcal{N}(\mathbf{y} | X\beta, \sigma_2 (\delta K + I))$$

where $\tau^2 = \delta\sigma^2$.

We need to deal with this unfriendly form of likelihood:

$$-\frac{1}{2} \left(n \log(2\pi\sigma^2) + \log |I + \delta K| + \frac{1}{\sigma^2} [\mathbf{y} - X\beta]^\top (I + \delta K)^{-1} [\mathbf{y} - X\beta] \right)$$

FaST Linear Mixed Model (Lippert *et al.* 2011)

Instead, we can transform the underlying distribution using spectral decomposition of the genetic-relatedness matrix (GRM),

$K = USU^\top$ where $U^\top U = I$, and S is a diagonal matrix.

$$\begin{array}{ccc} U^\top \mathbf{y} & \sim & \mathcal{N}\left(\begin{array}{cc} U^\top X & \beta \\ \text{projected genotype} & \end{array} \middle| \sigma^2 U^\top (I + \delta K) U \right) \\ \text{projected output} & & \end{array}$$

Lippert, Listgarten, .. , Heckerman, *Nature Methods* (2011)

FaST Linear Mixed Model (Lippert *et al.* 2011)

Instead, we can transform the underlying distribution using spectral decomposition of the genetic-relatedness matrix (GRM),

$K = USU^\top$ where $U^\top U = I$, and S is a diagonal matrix.

$$\begin{aligned} U^\top \mathbf{y} &\sim \mathcal{N}\left(\begin{array}{c} U^\top X \\ \text{projected genotype} \end{array}, \beta, \sigma^2 U^\top (I + \delta K) U \right) \\ (\text{by the affine transformation}) &\sim \mathcal{N}\left(\begin{array}{c} U^\top X \\ \text{projected genotype} \end{array}, \beta, \sigma^2 (I + \delta S) \right) \end{aligned}$$

- ▶ We can find β by weighted least square
- ▶ We can find σ^2 and δ by fixing β

A key research question in LMM: What covariance matrix?

If there were many types of random effects,

$$\mathbf{y} = \underset{\text{fixed}}{X\beta} + \underset{\text{random effects}}{\mathbf{u} + \mathbf{w} + \dots} + \underset{\text{unknown}}{\epsilon}$$

A key research question in LMM: What covariance matrix?

If there were many types of random effects,

$$\mathbf{y} = \underset{\text{fixed}}{X\beta} + \underset{\text{random effects}}{\mathbf{u} + \mathbf{w} + \dots} + \underset{\text{unknown}}{\epsilon}$$

We would need to many covariance matrices:

$$\mathbf{y}| \cdot \sim \mathcal{N} \left(X\beta, \sigma^2 \left(I + \underbrace{\delta_u K_u + \delta_w K_w + \dots}_{\text{random effects}} \right) \right)$$

A key research question in LMM: What covariance matrix?

If there were many types of random effects,

$$\mathbf{y} = \underset{\text{fixed}}{X\beta} + \underset{\text{random effects}}{\mathbf{u} + \mathbf{w} + \dots} + \underset{\text{unknown}}{\epsilon}$$

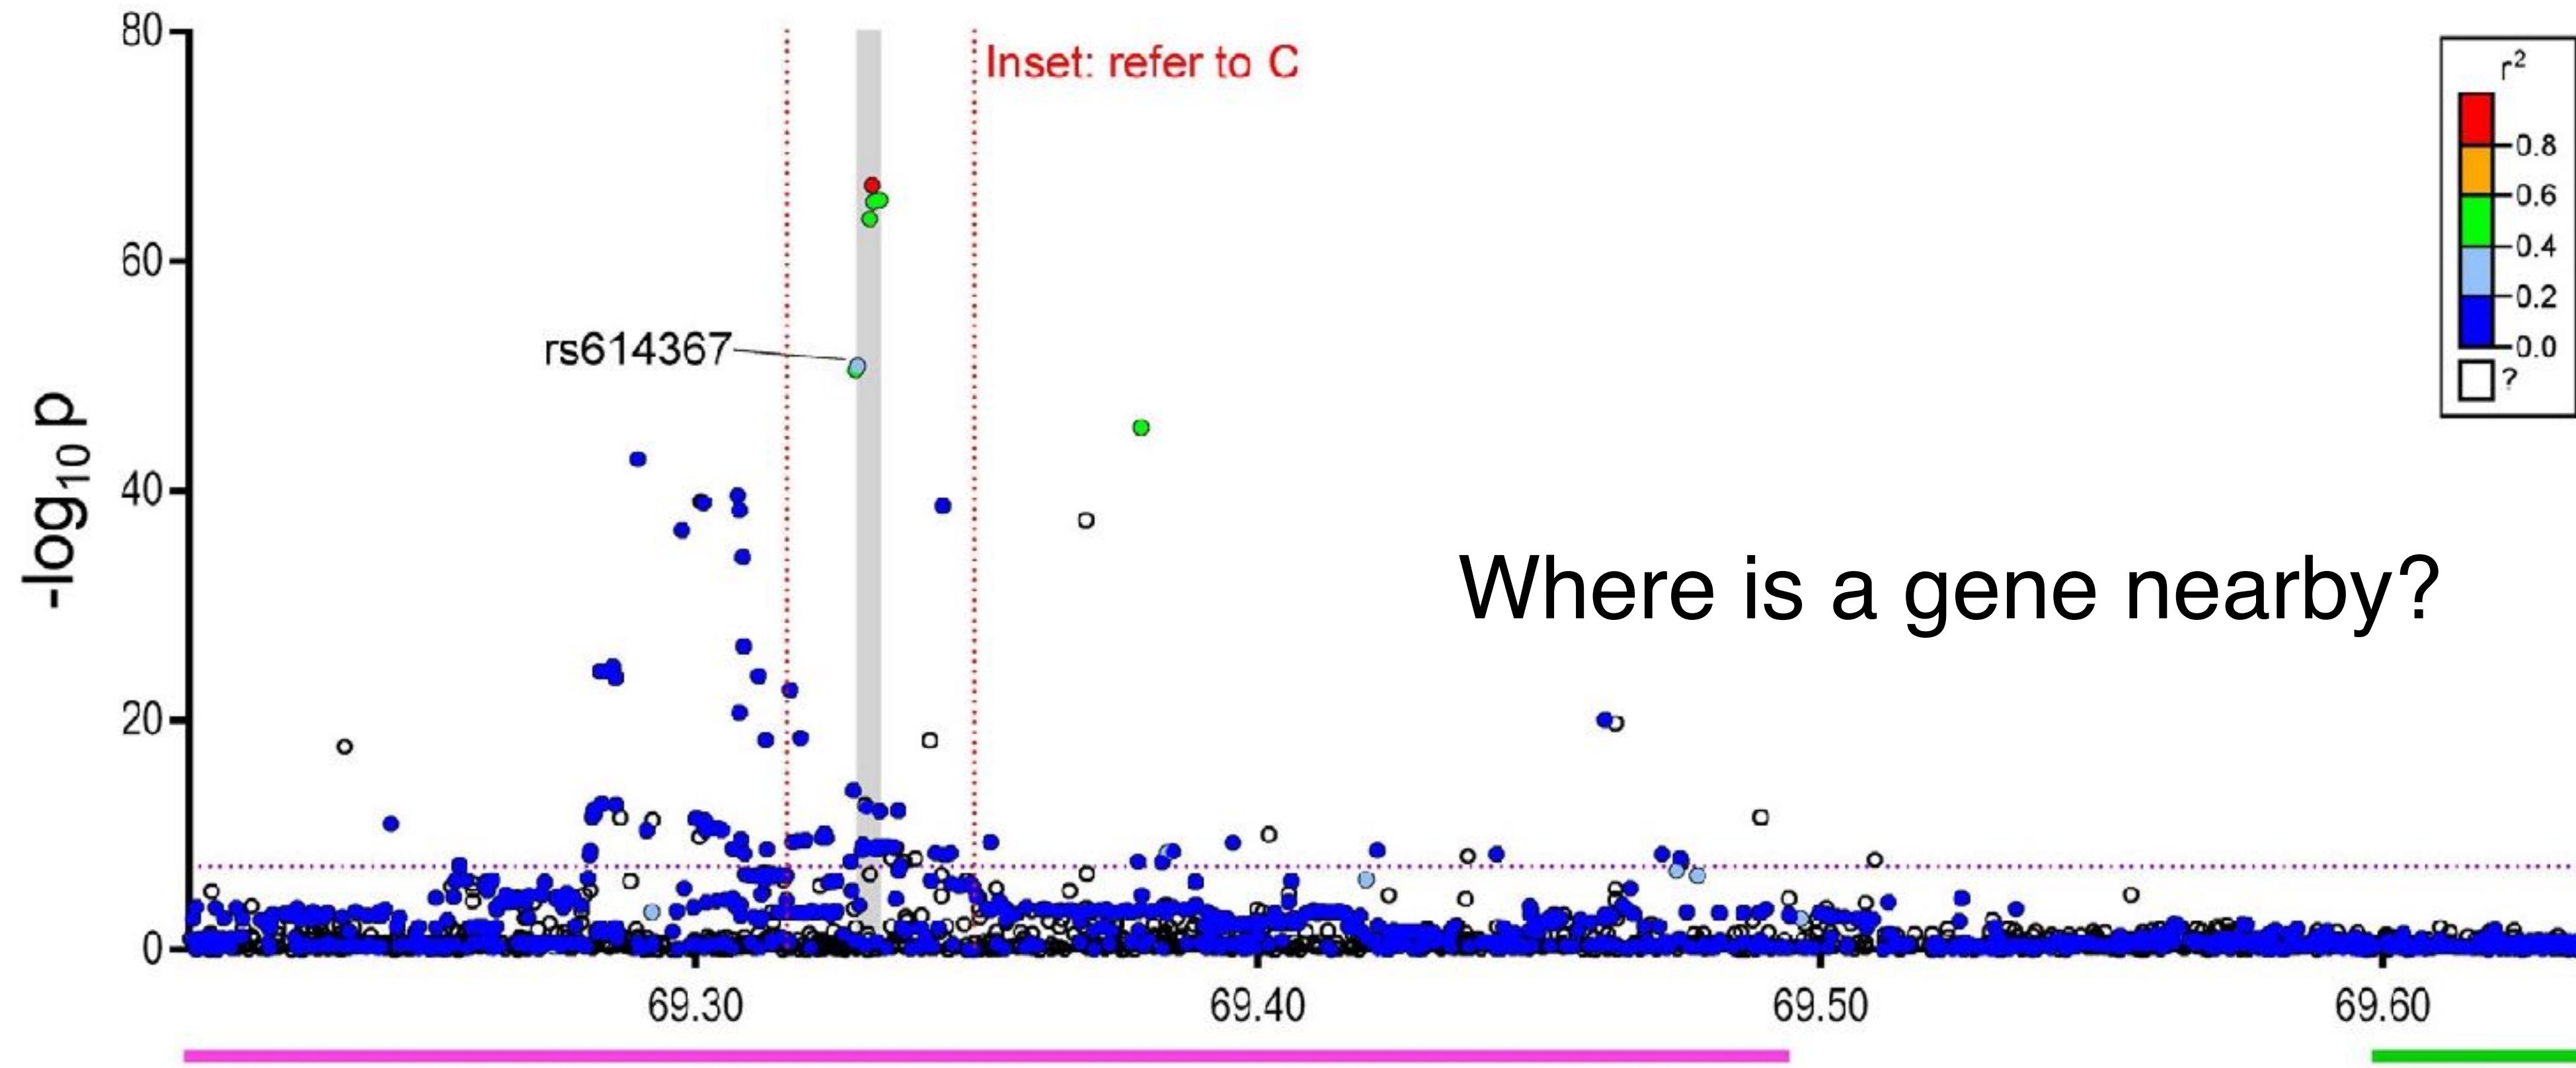

We would need to many covariance matrices:

$$\mathbf{y}| \cdot \sim \mathcal{N}\left(X\beta, \sigma^2(I + \underbrace{\delta_u K_u + \delta_w K_w + \dots}_{\text{random effects}})\right)$$

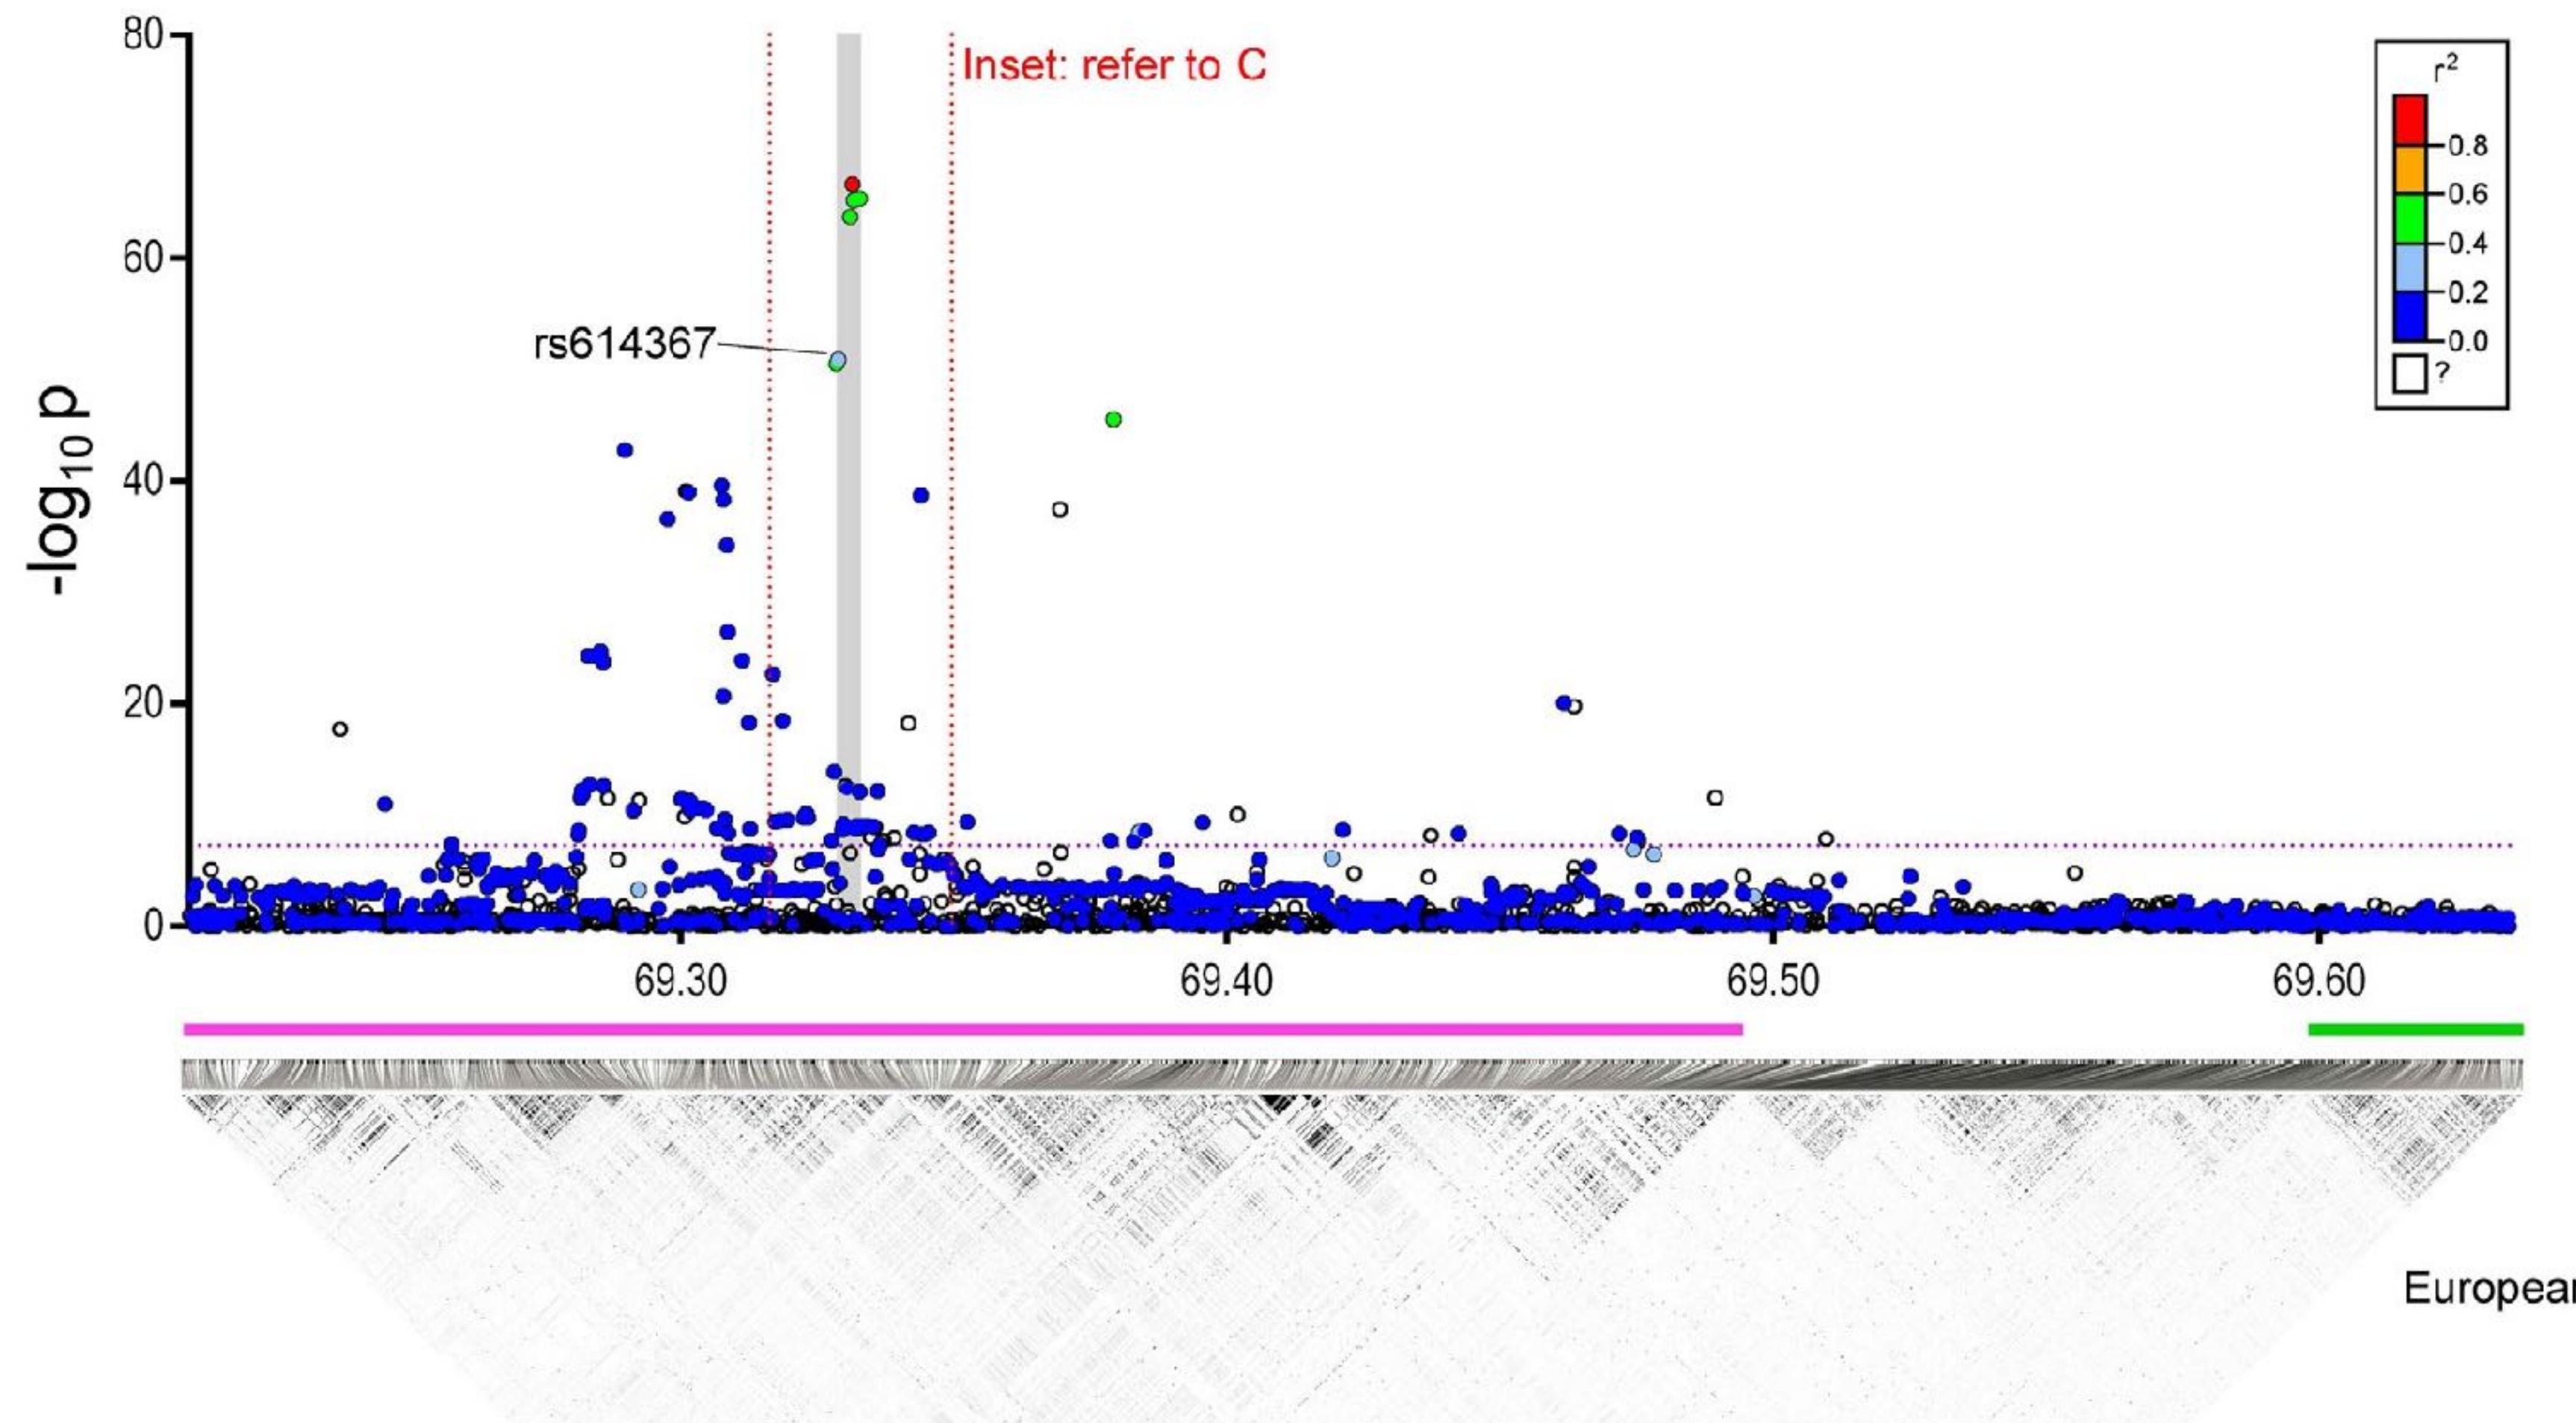

If we only care about variance decomposition $\beta_j \sim \mathcal{N}(0, \tau)$:

$$\mathbf{y} \sim \mathcal{N}\left(0, \sigma^2 \left(\frac{\sigma_{\text{genetic}}^2}{n} \mathbf{X} \mathbf{X}^\top + I + \underbrace{\delta_u K_u + \delta_w K_w + \dots}_{\text{random effects}}\right)\right)$$

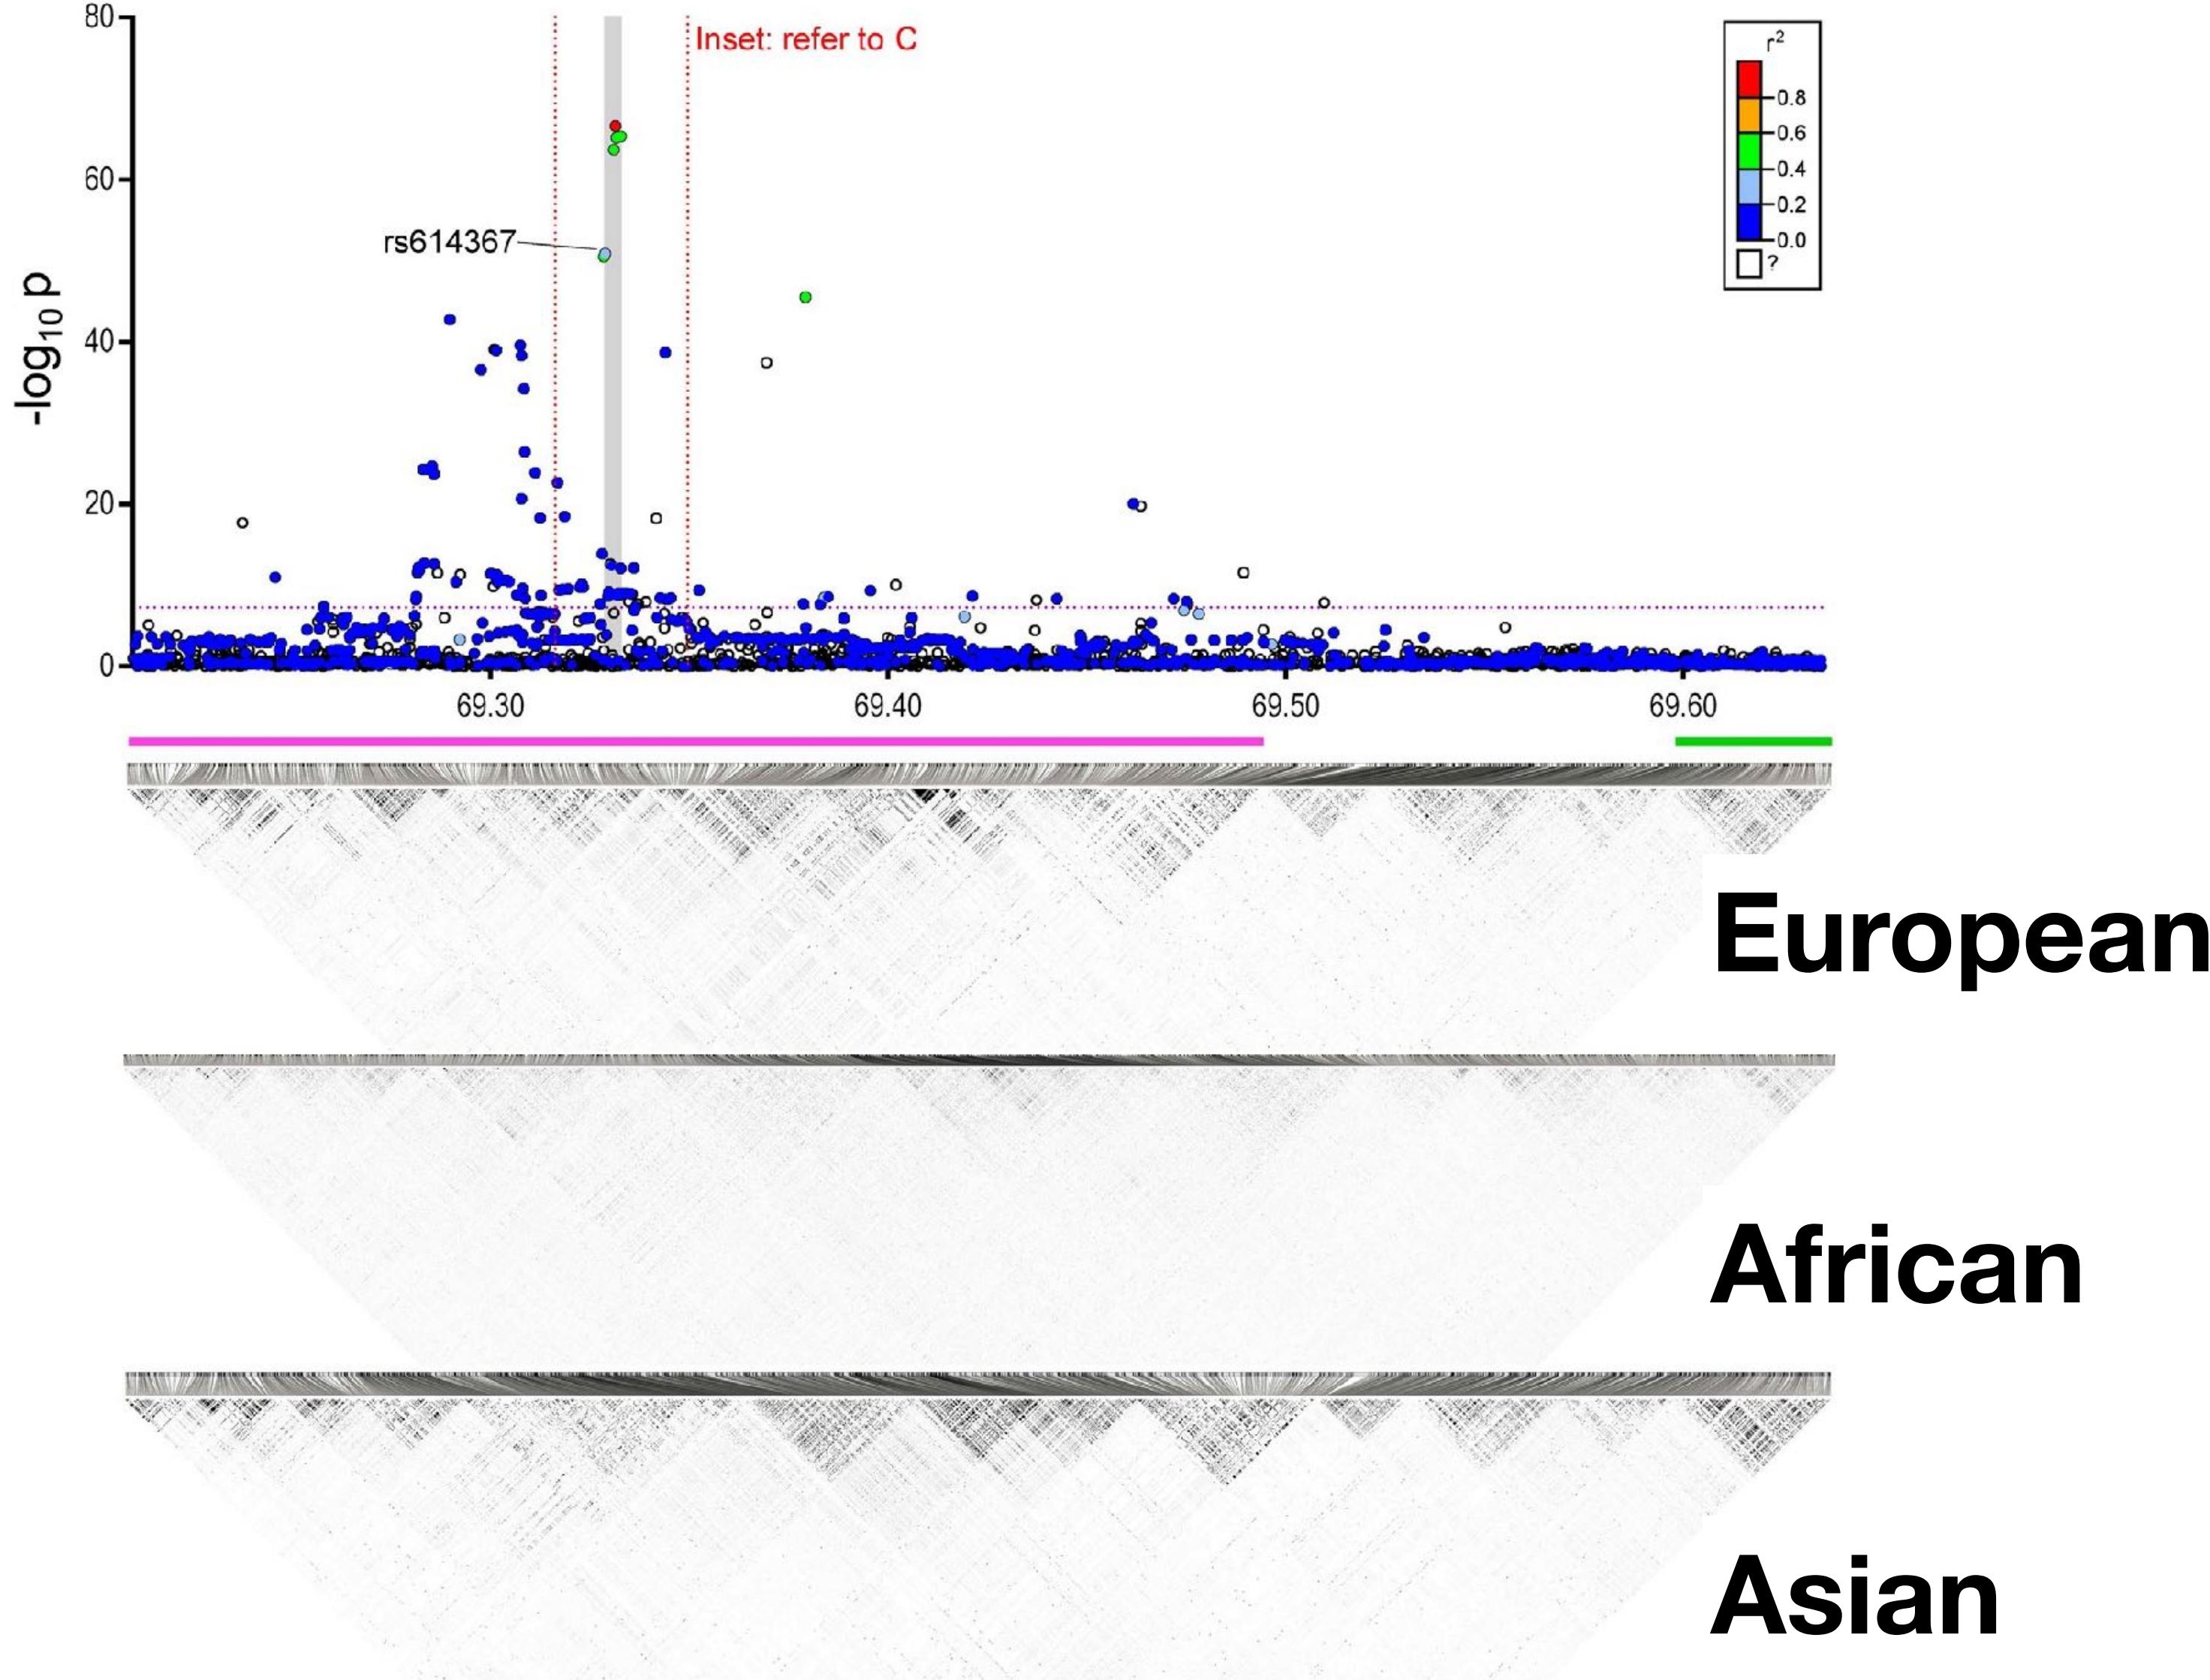

90% of GWAS hits on the non-coding regions

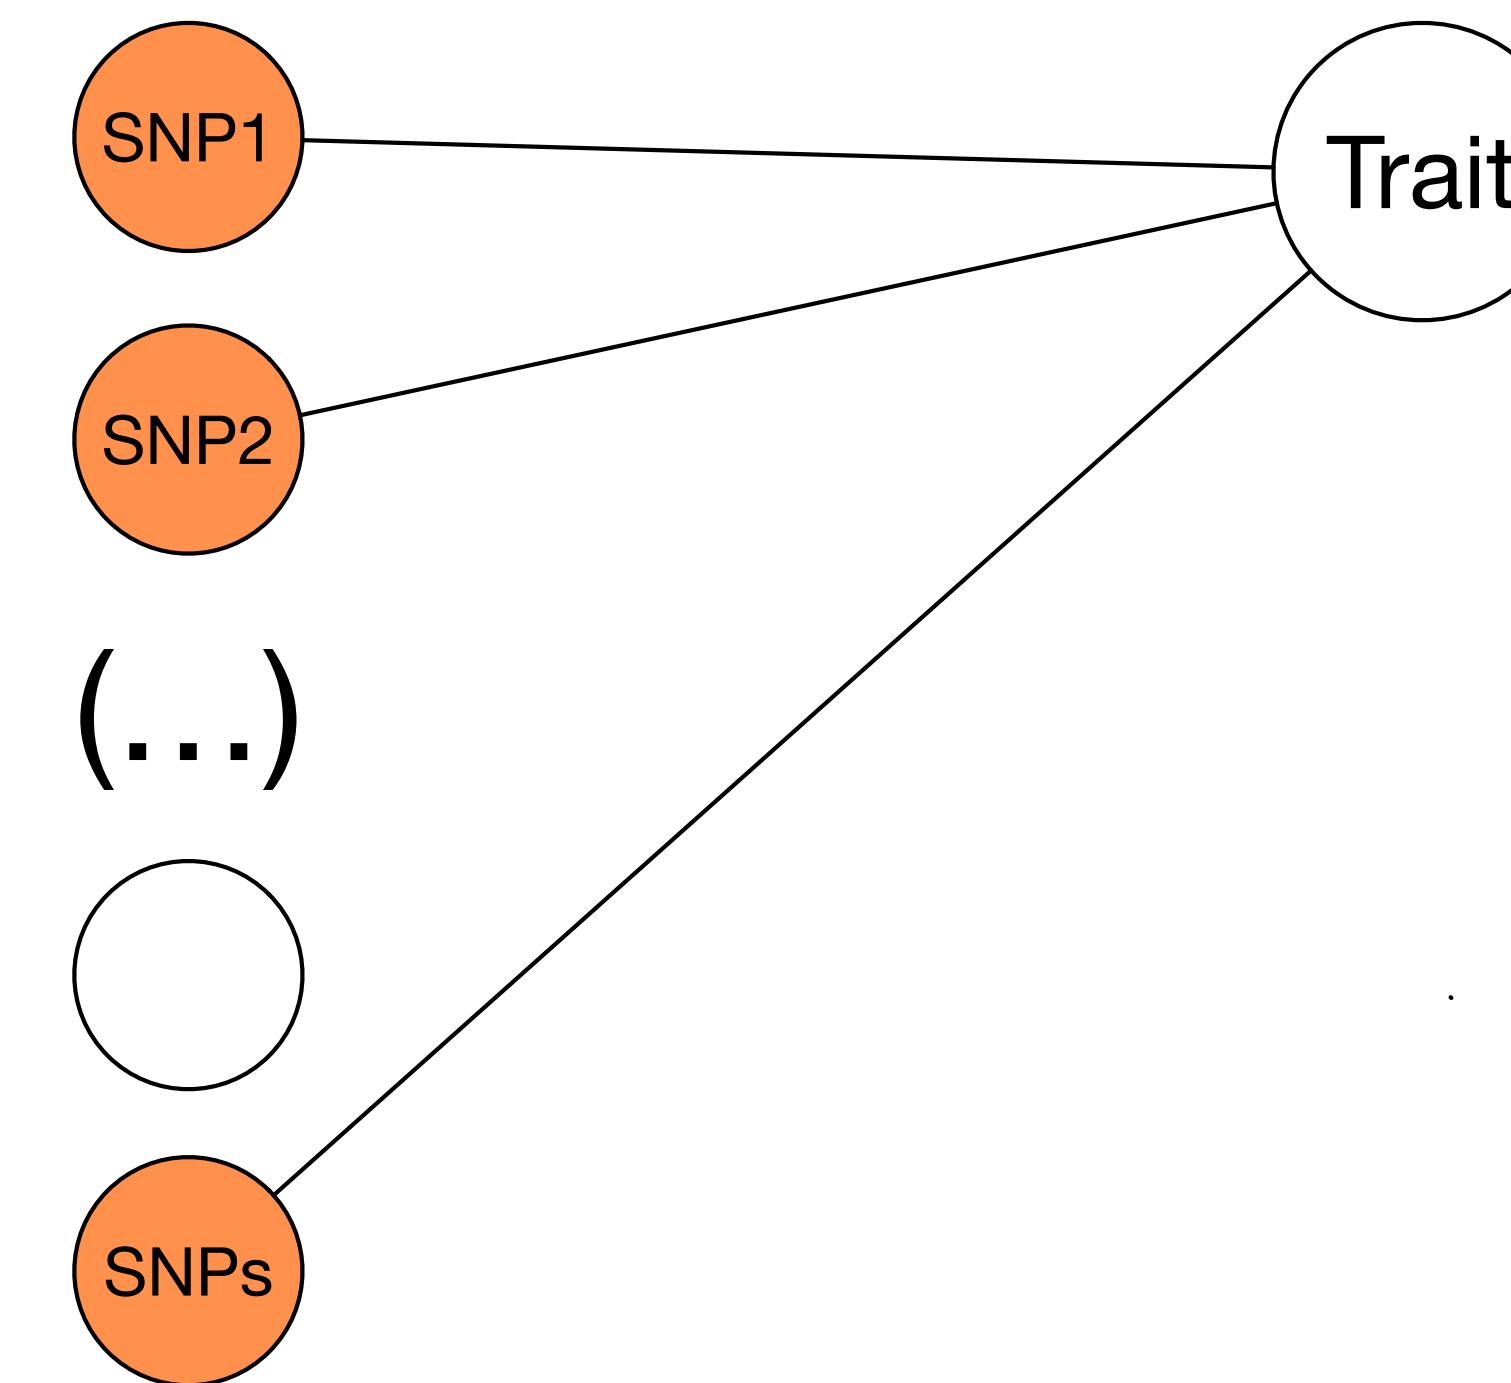

LD structure, many significantly associated variants

Different population structures, different LD patterns

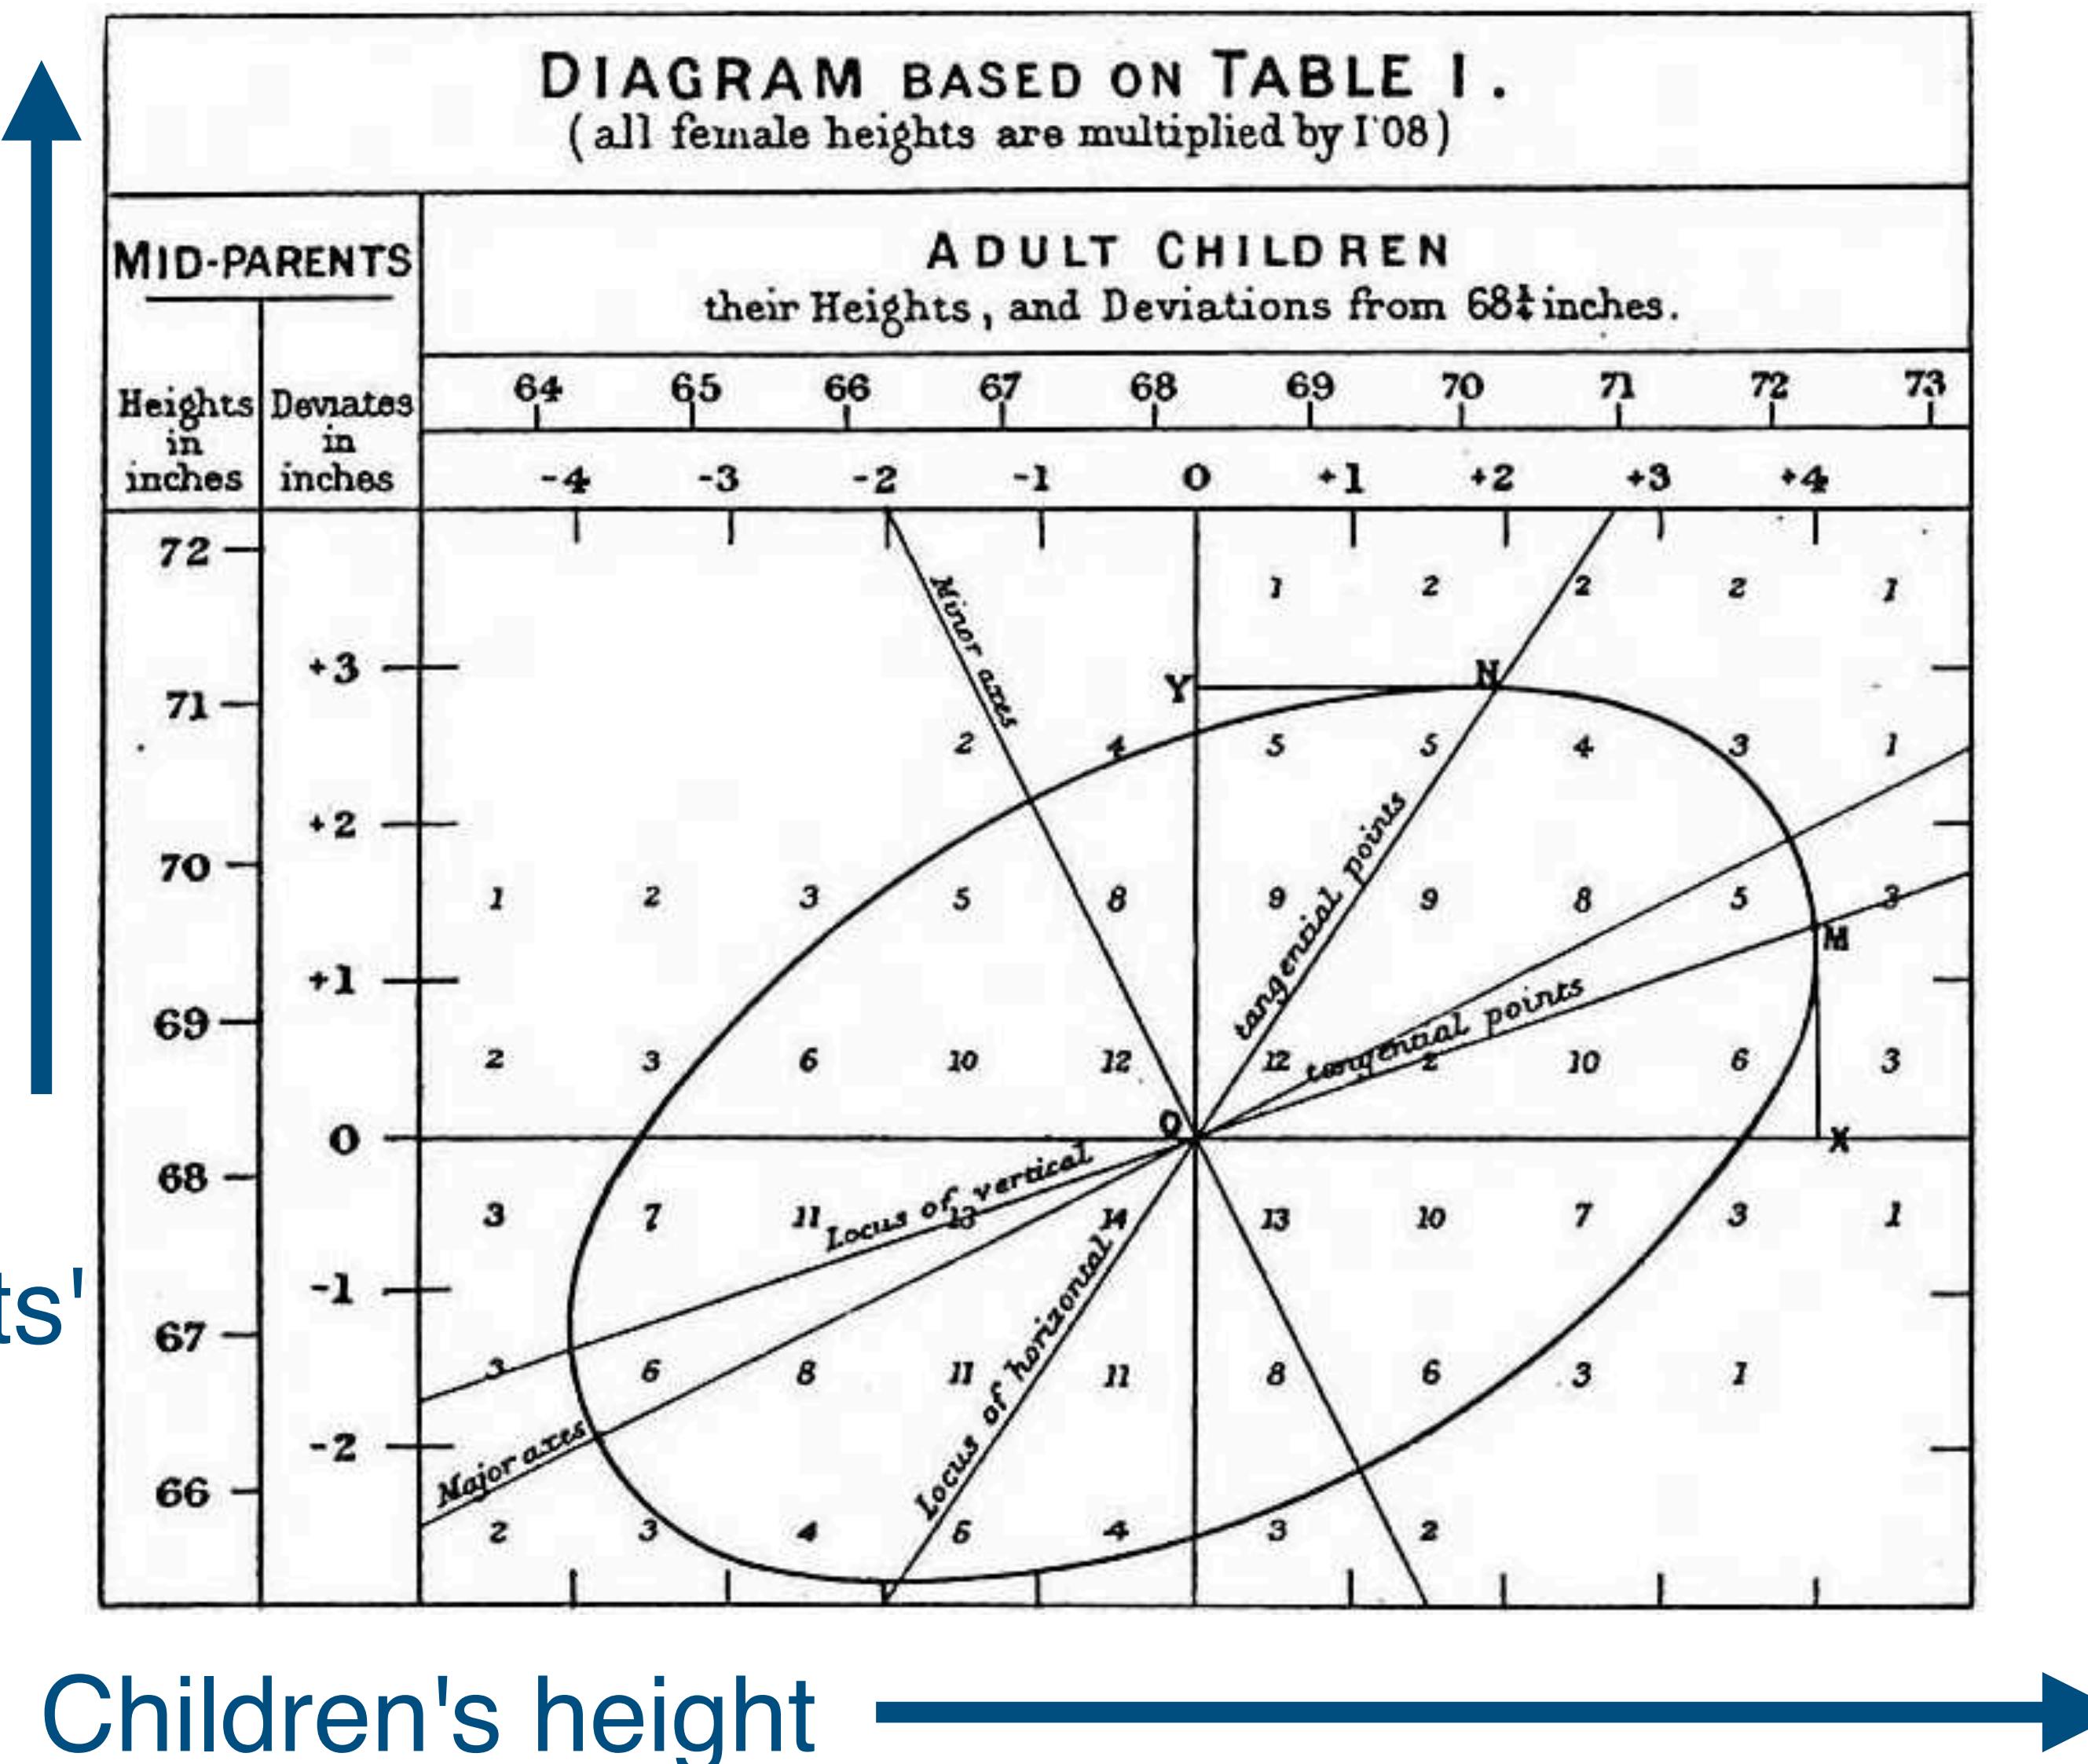

Many complex traits are polygenic

Galton's regression model finally confirmed

Parents' height

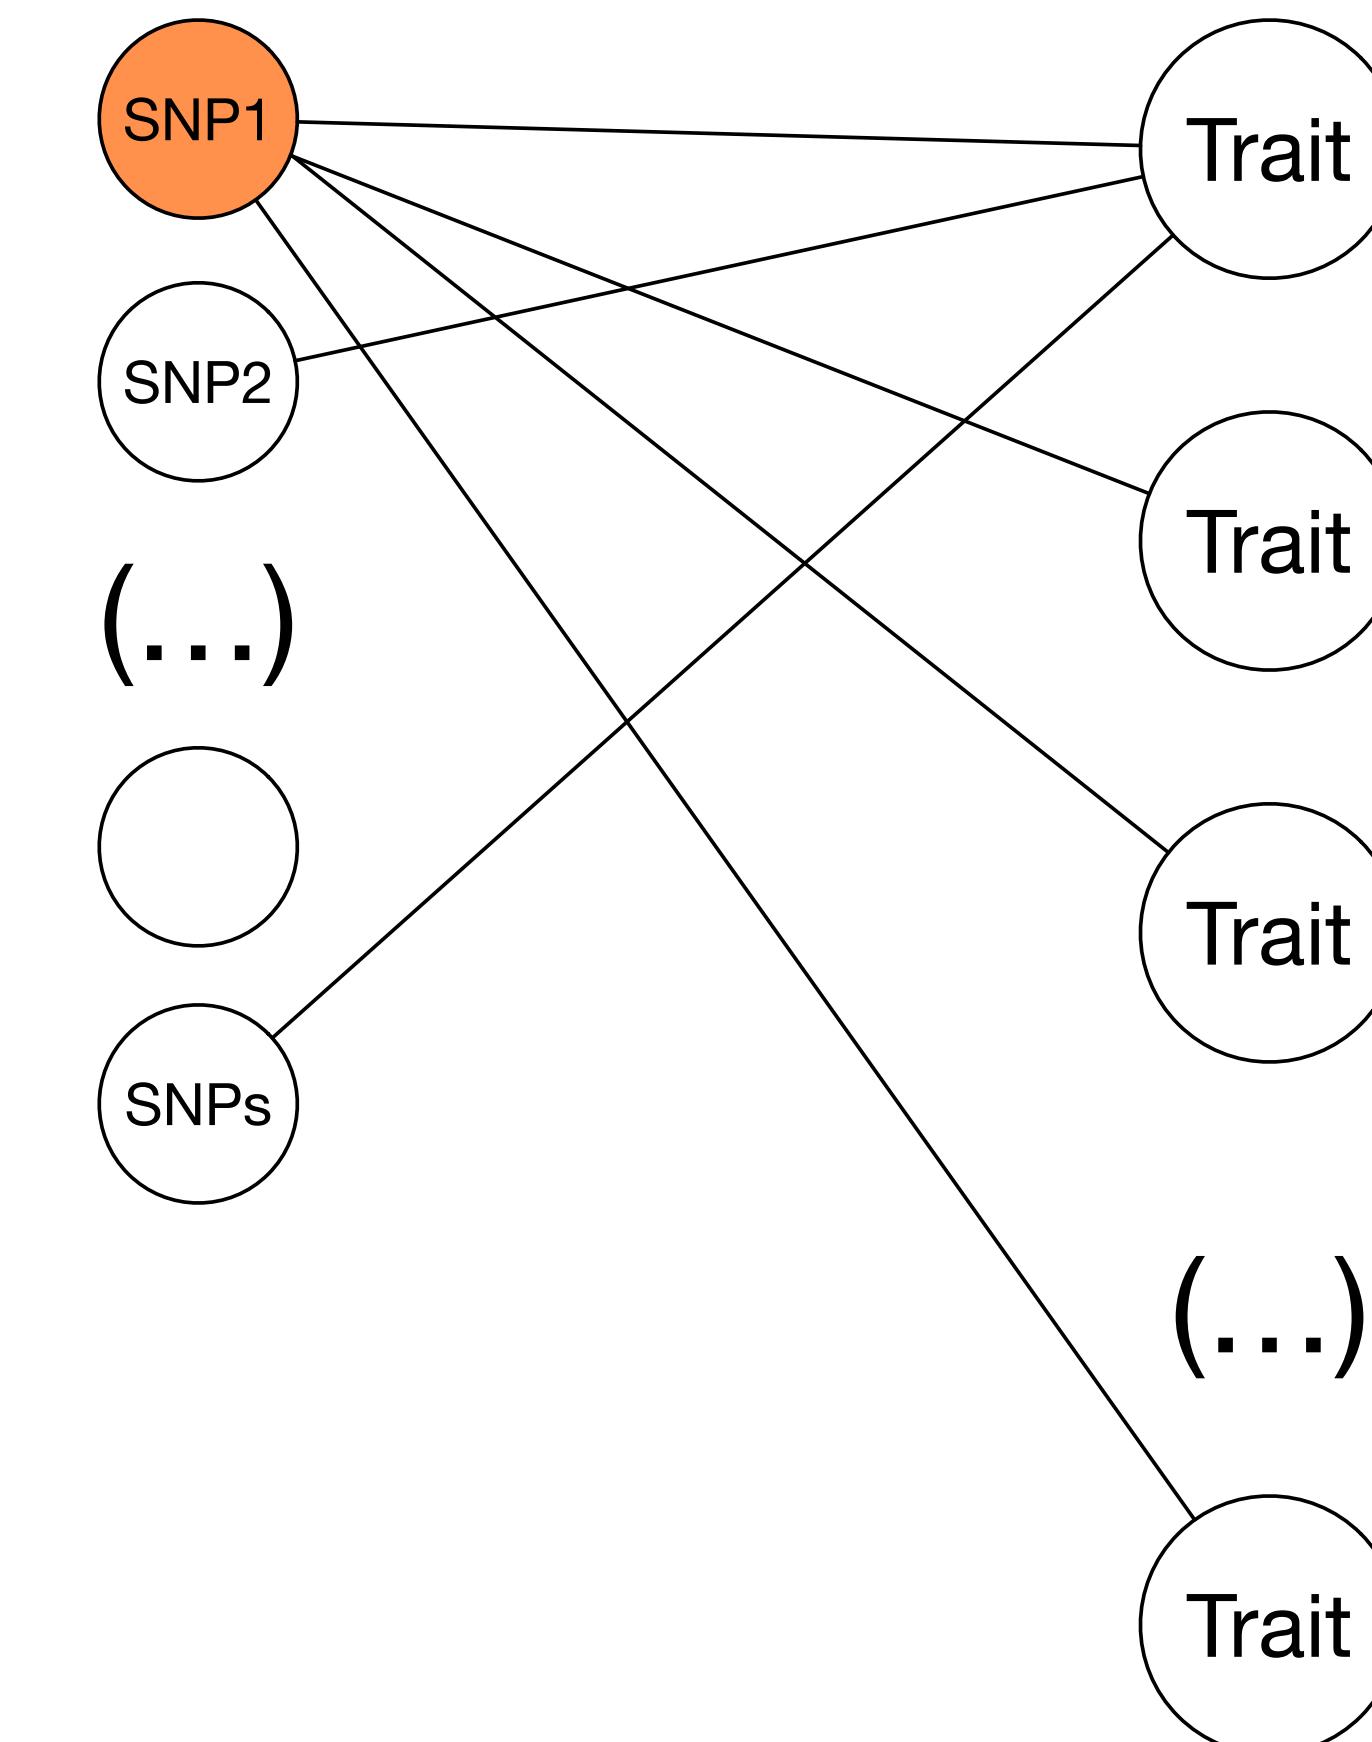

Is there a "tall/small" gene?

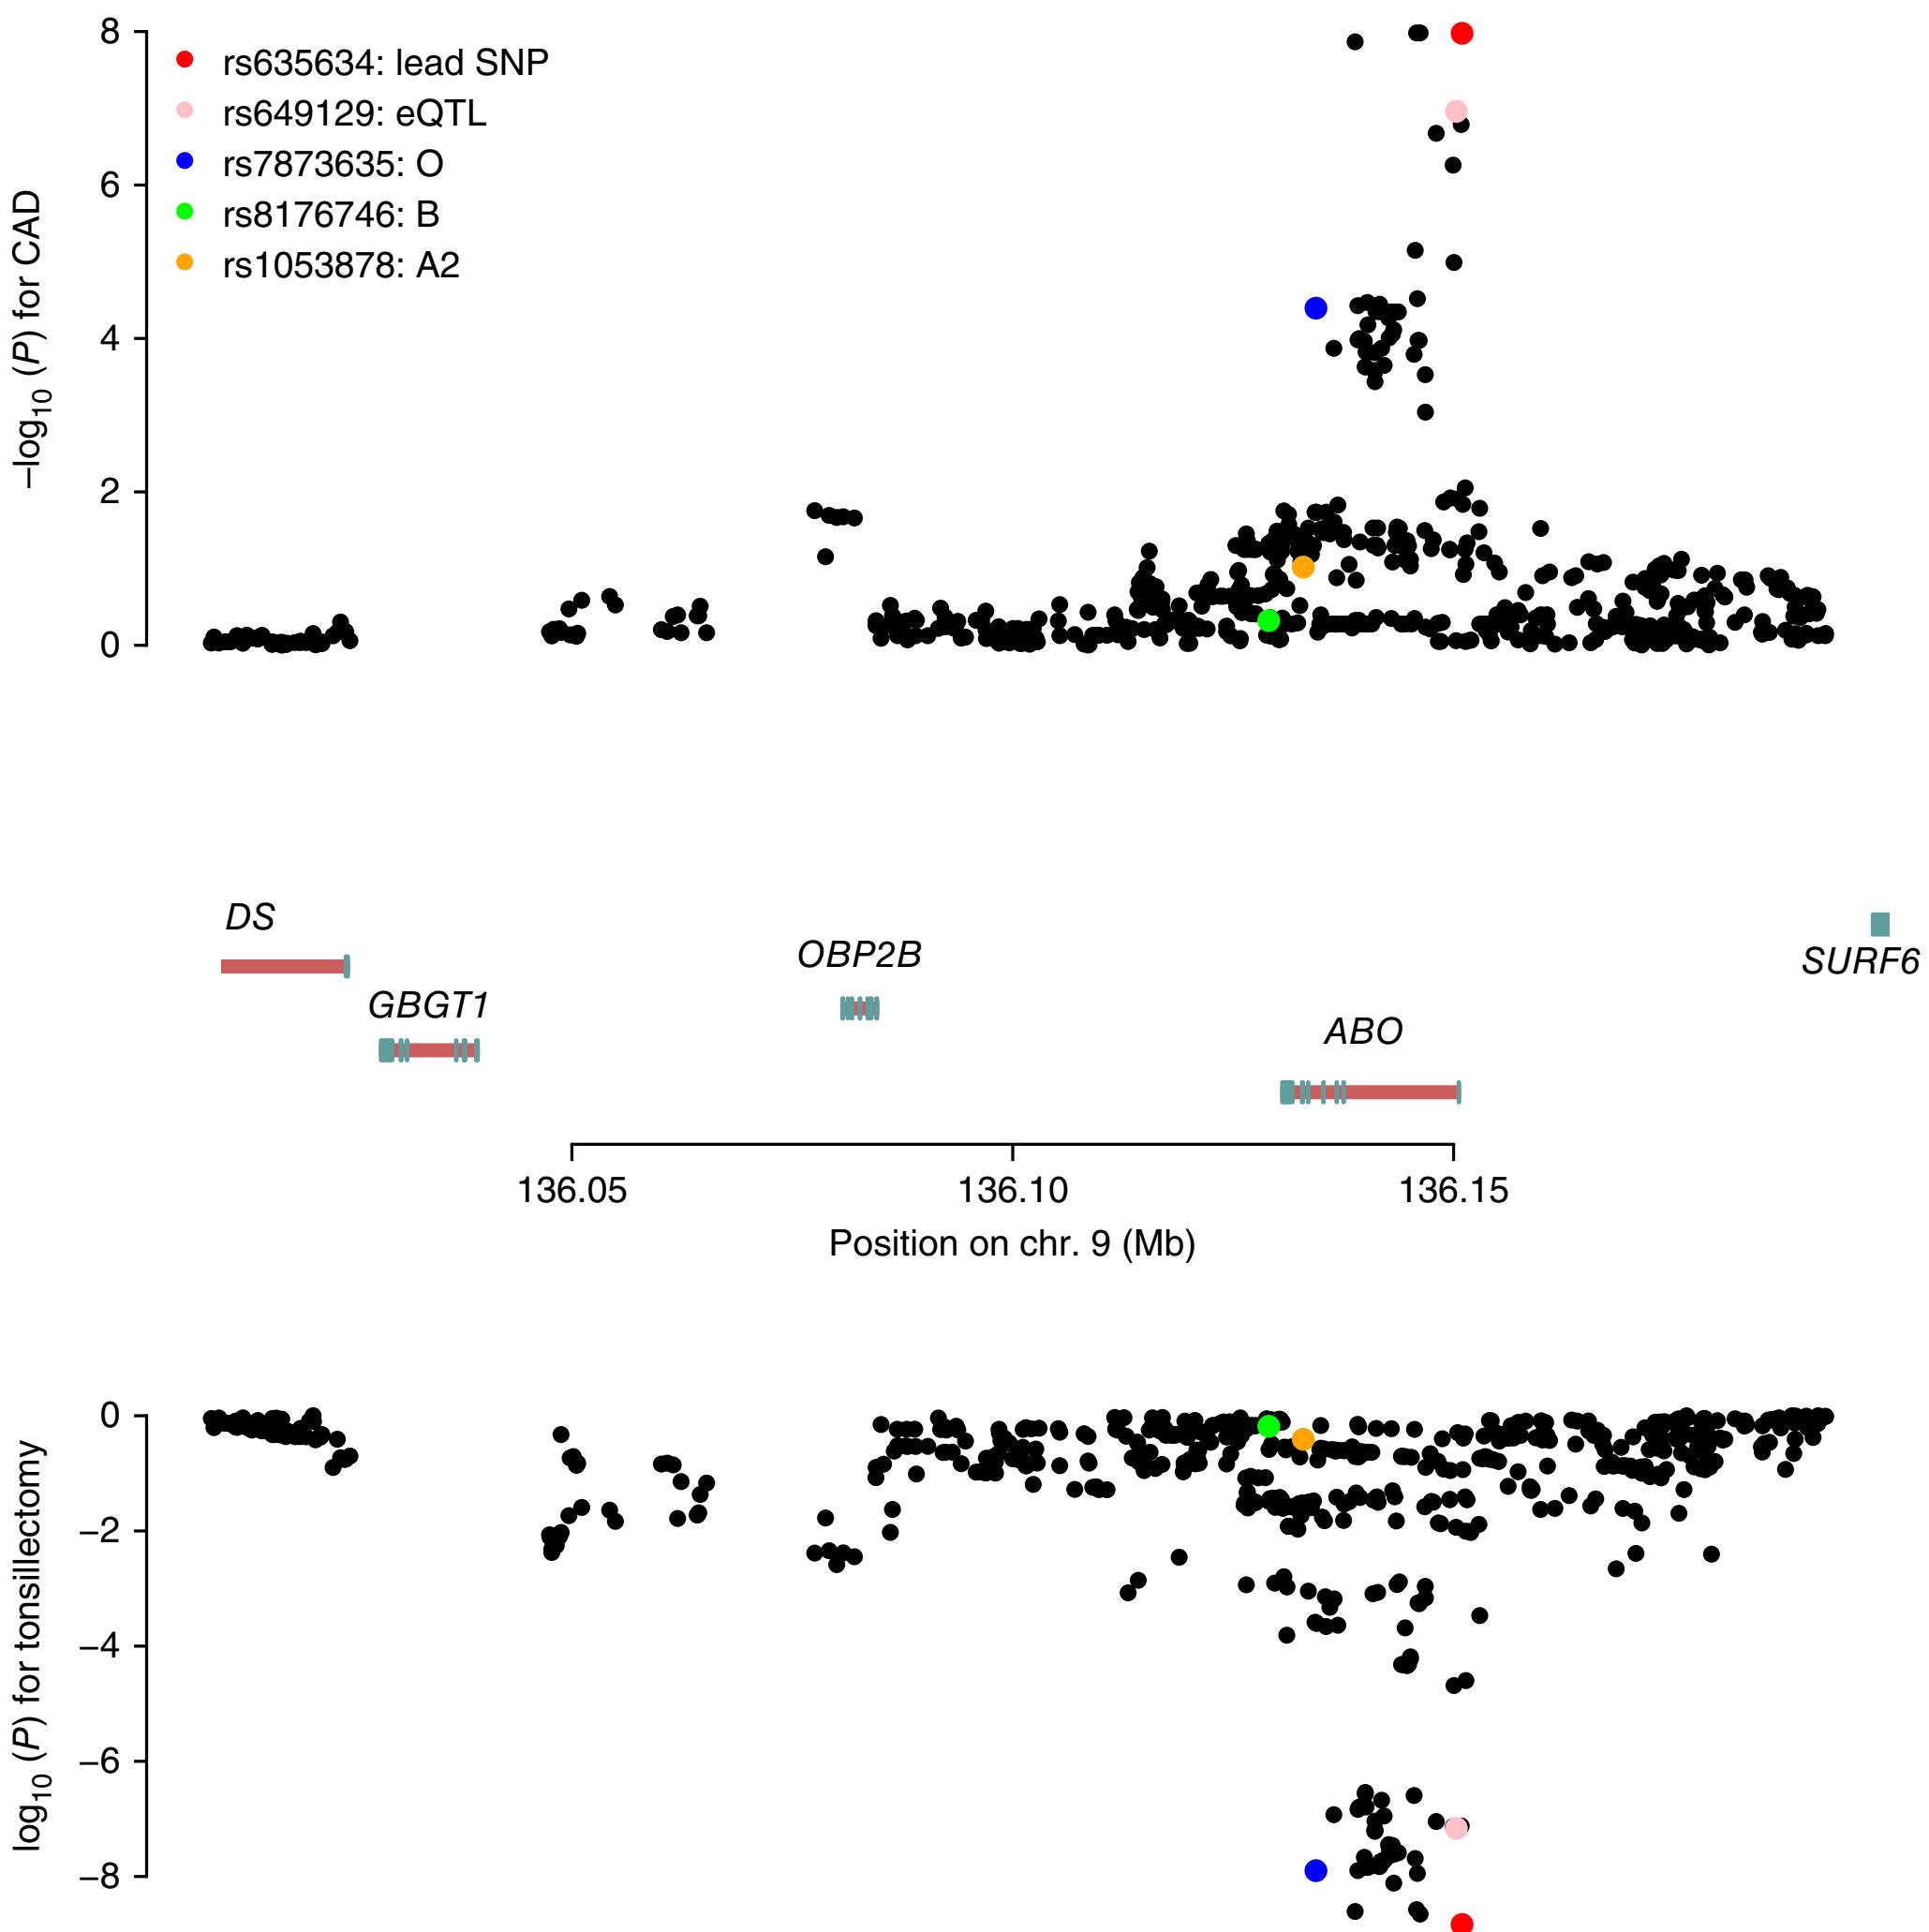

A single variant may act on many traits

Pleiotropy

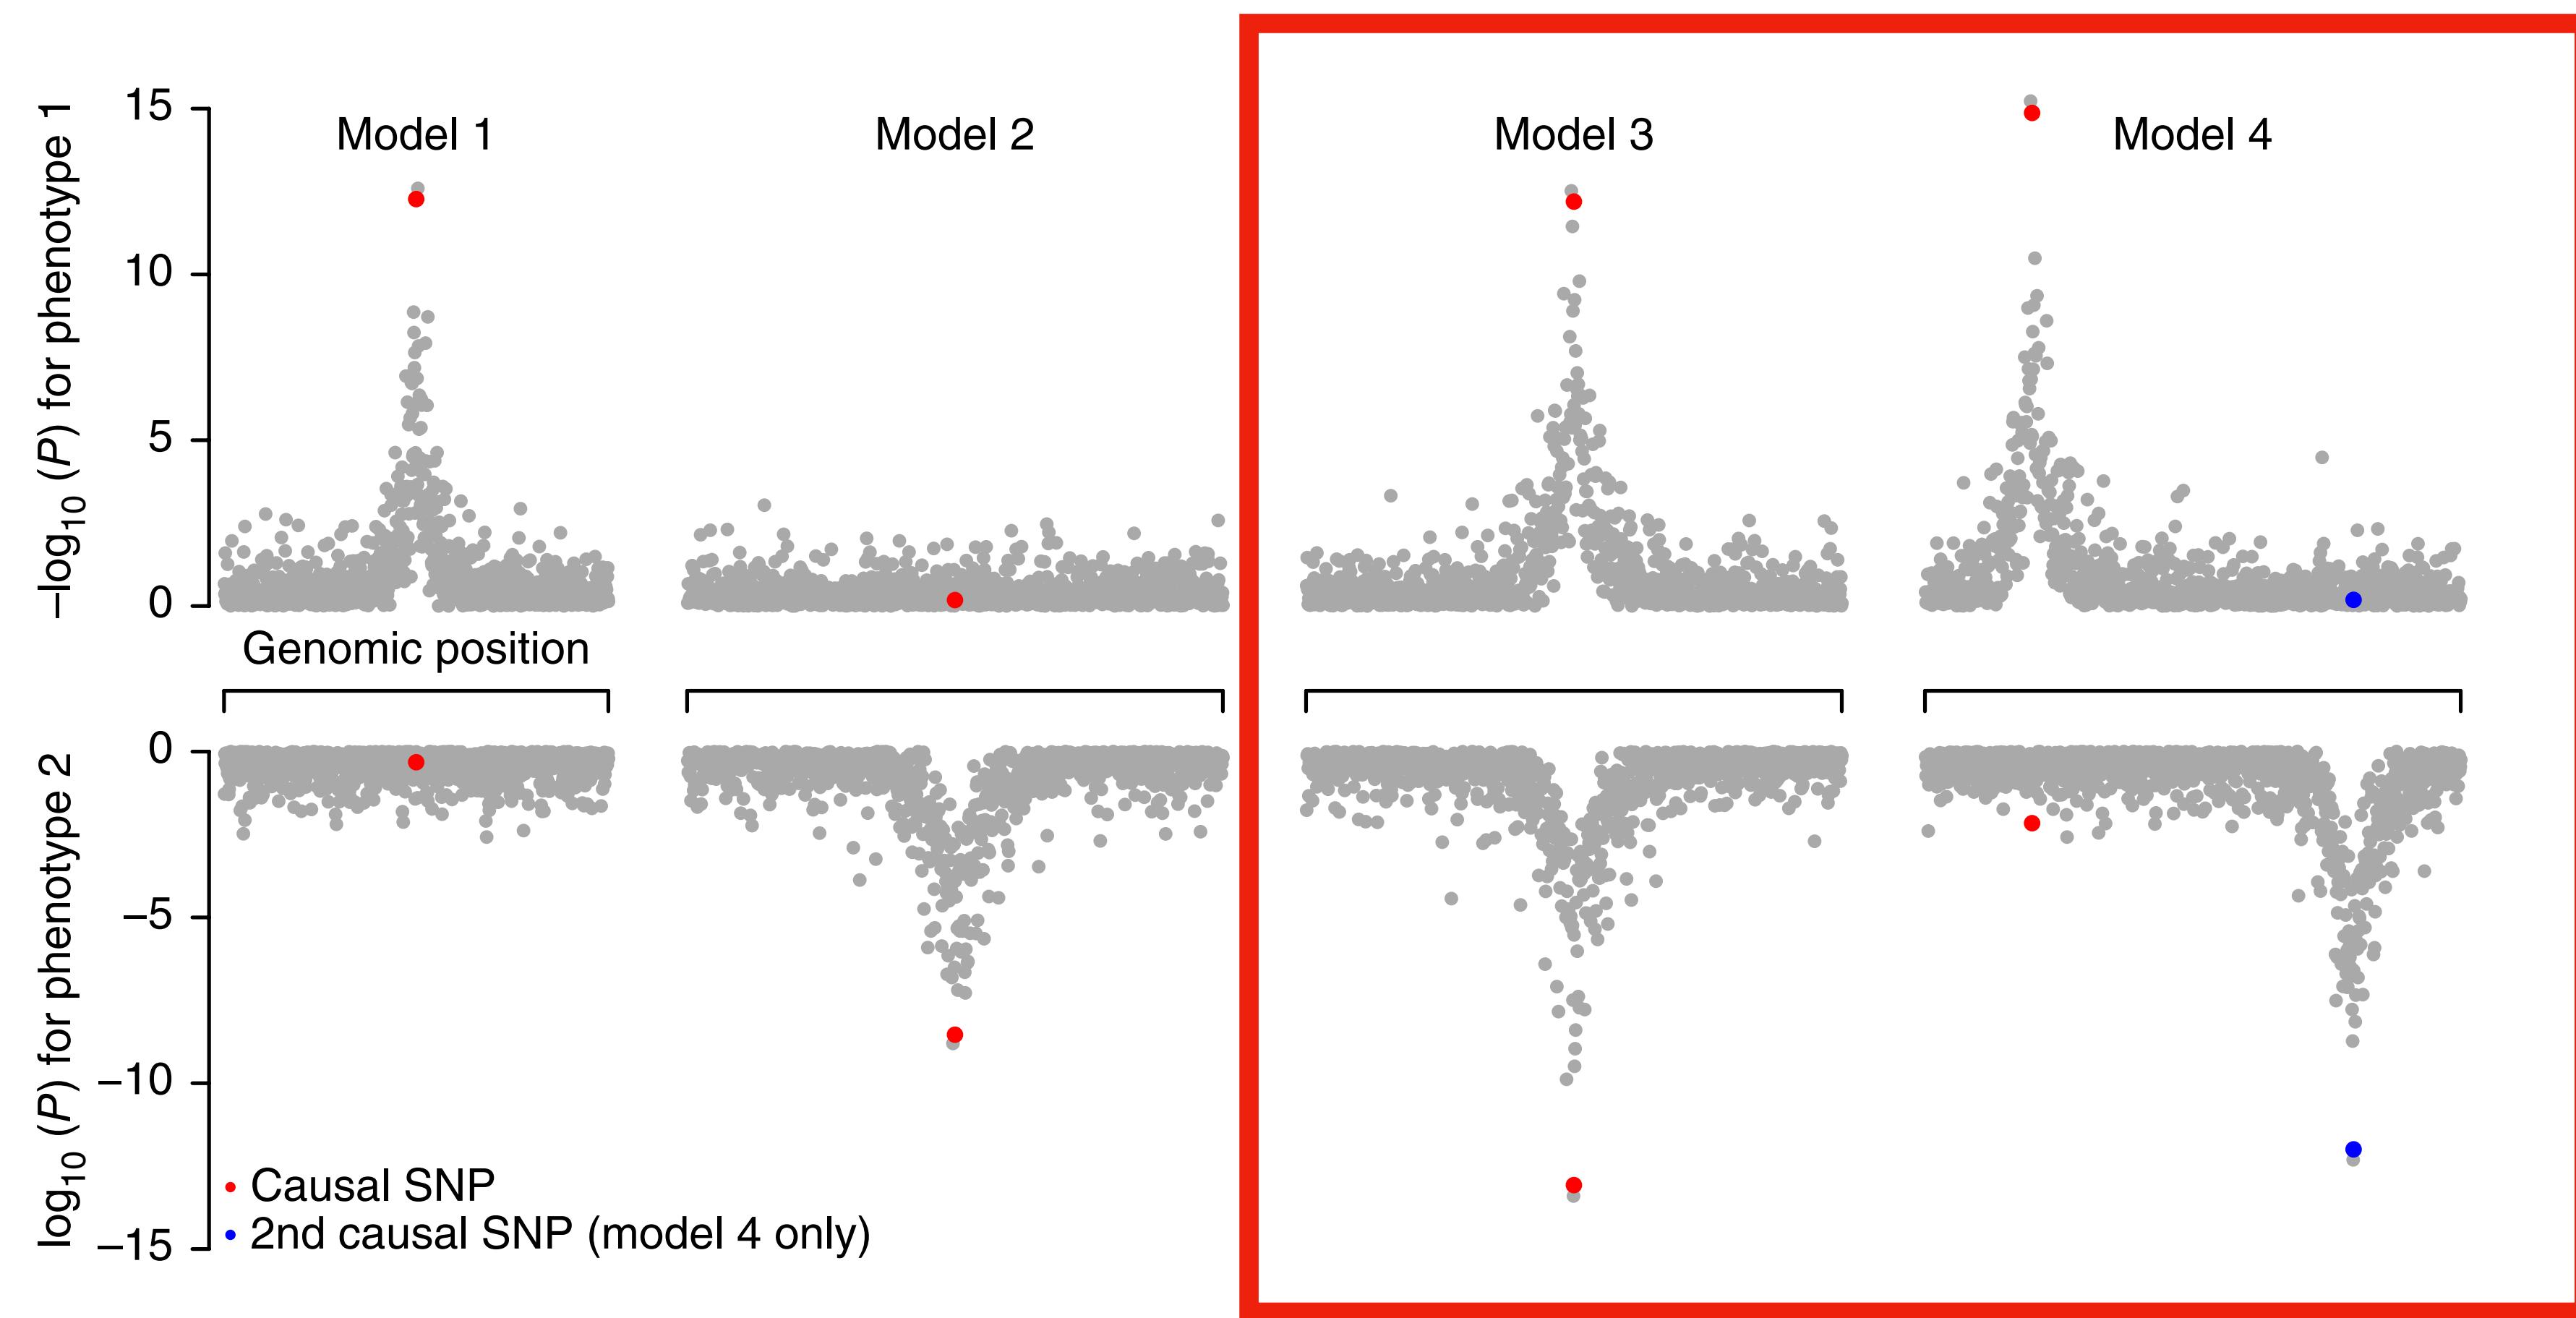

A single variant is associated, over and over with many different human traits!

A single variant may act on many traits

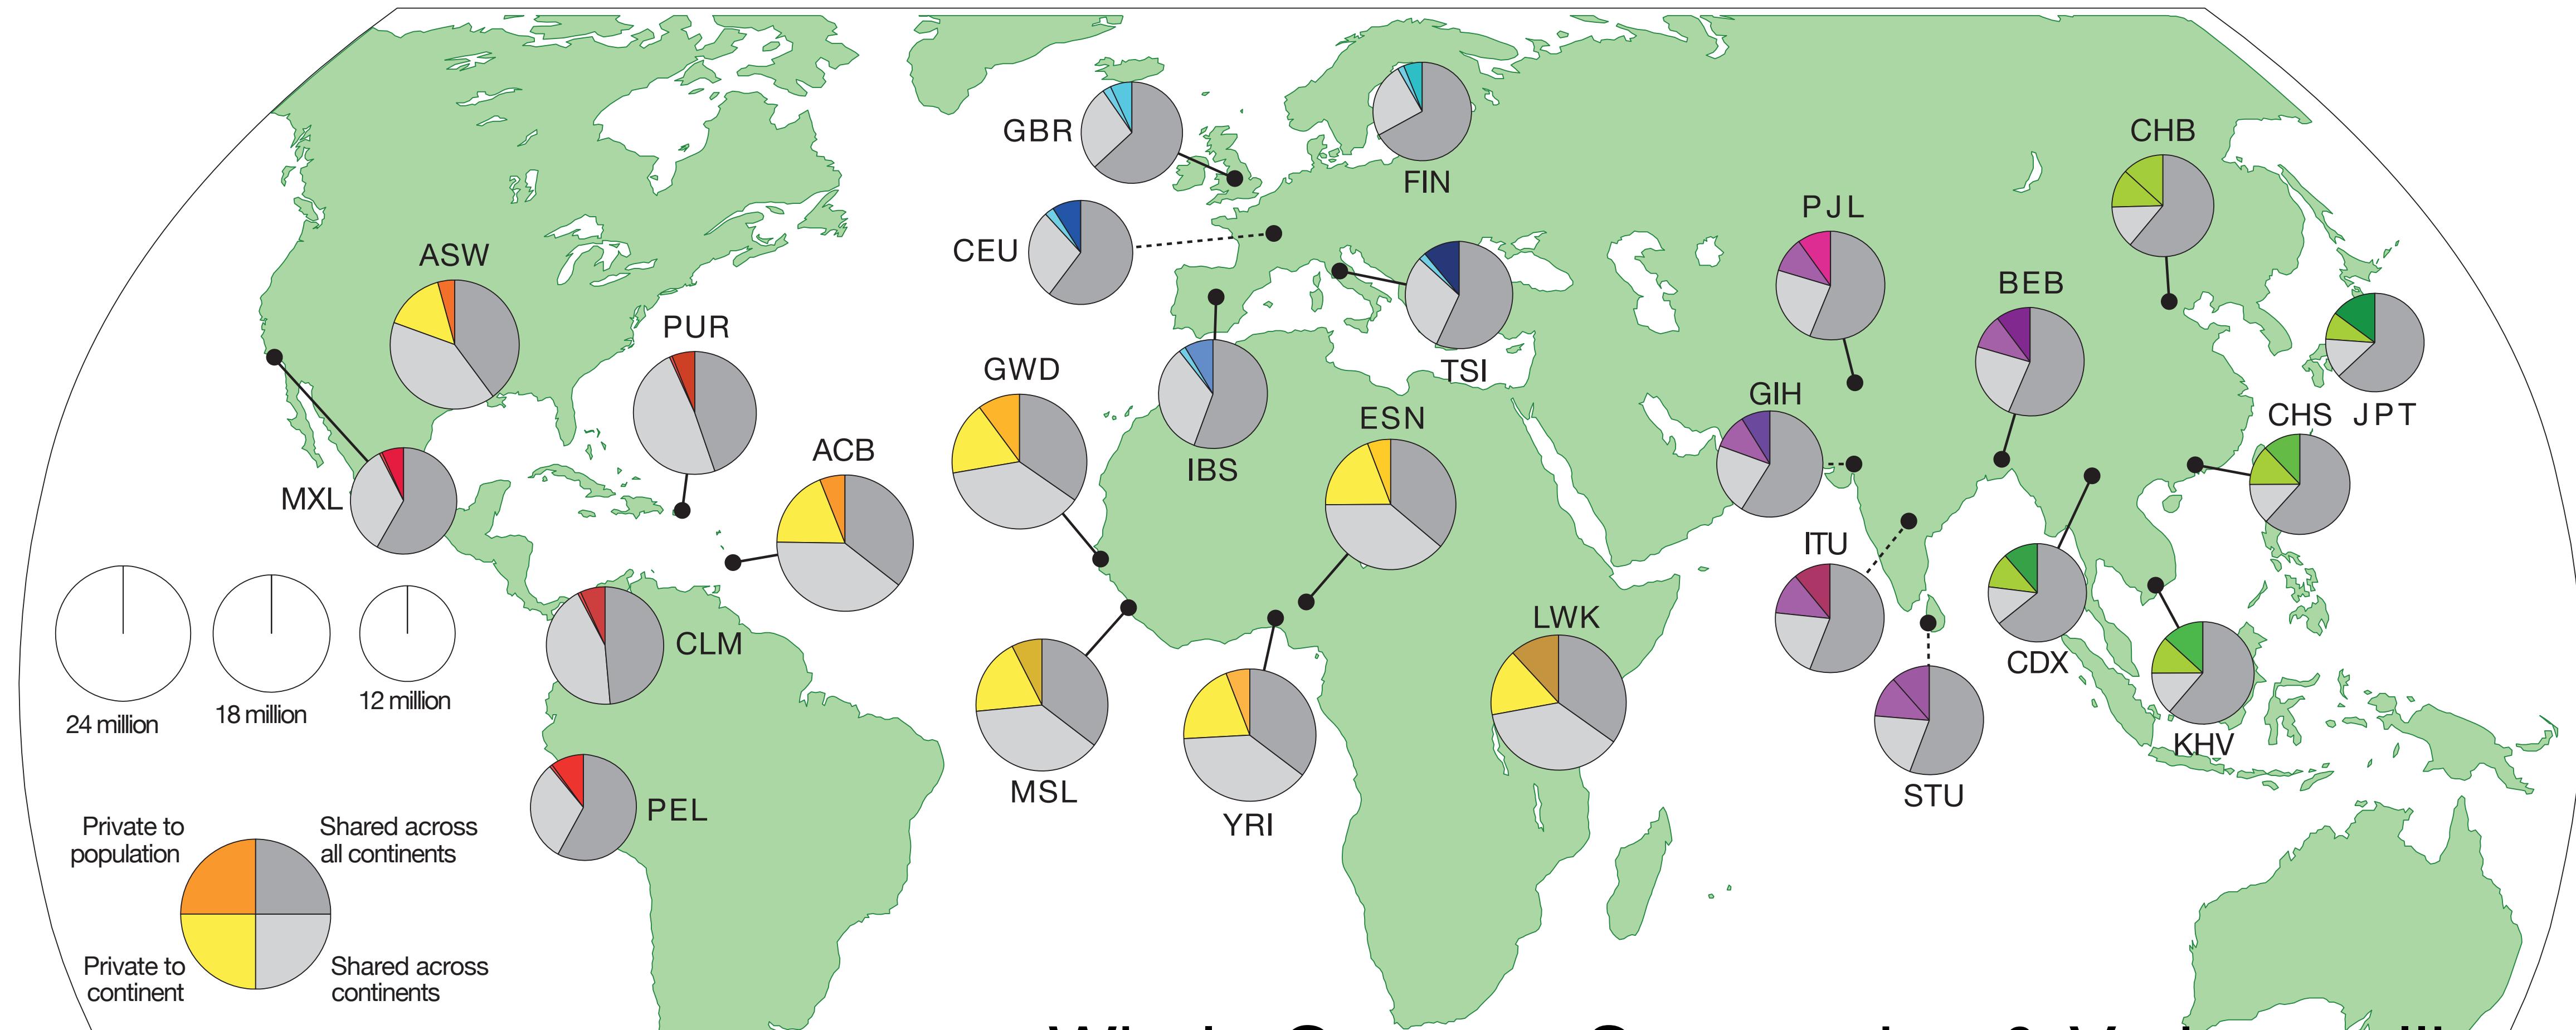

A single variant may act on many traits

The 1000 genomes project

Whole Genome Sequencing & Variant calling
across 1000 individuals in many different groups

Much of human genetics problems centre on two covariance matrices

For a standardized $n \times p$ genotype matrix X (n : #individuals, p : #SNPs),

1. Genetic relatedness matrix (GRM)

individual by individual, $n \times n$ matrix

$$K \approx XX^\top/n$$

The matrix K captures population structure/correlation across different individuals.

- ▶ Kinship matrix; population admixture
- ▶ Human migration history

2. Linkage disequilibrium (LD)

SNP by SNP, $p \times p$ matrix

$$R \approx X^\top X/n$$

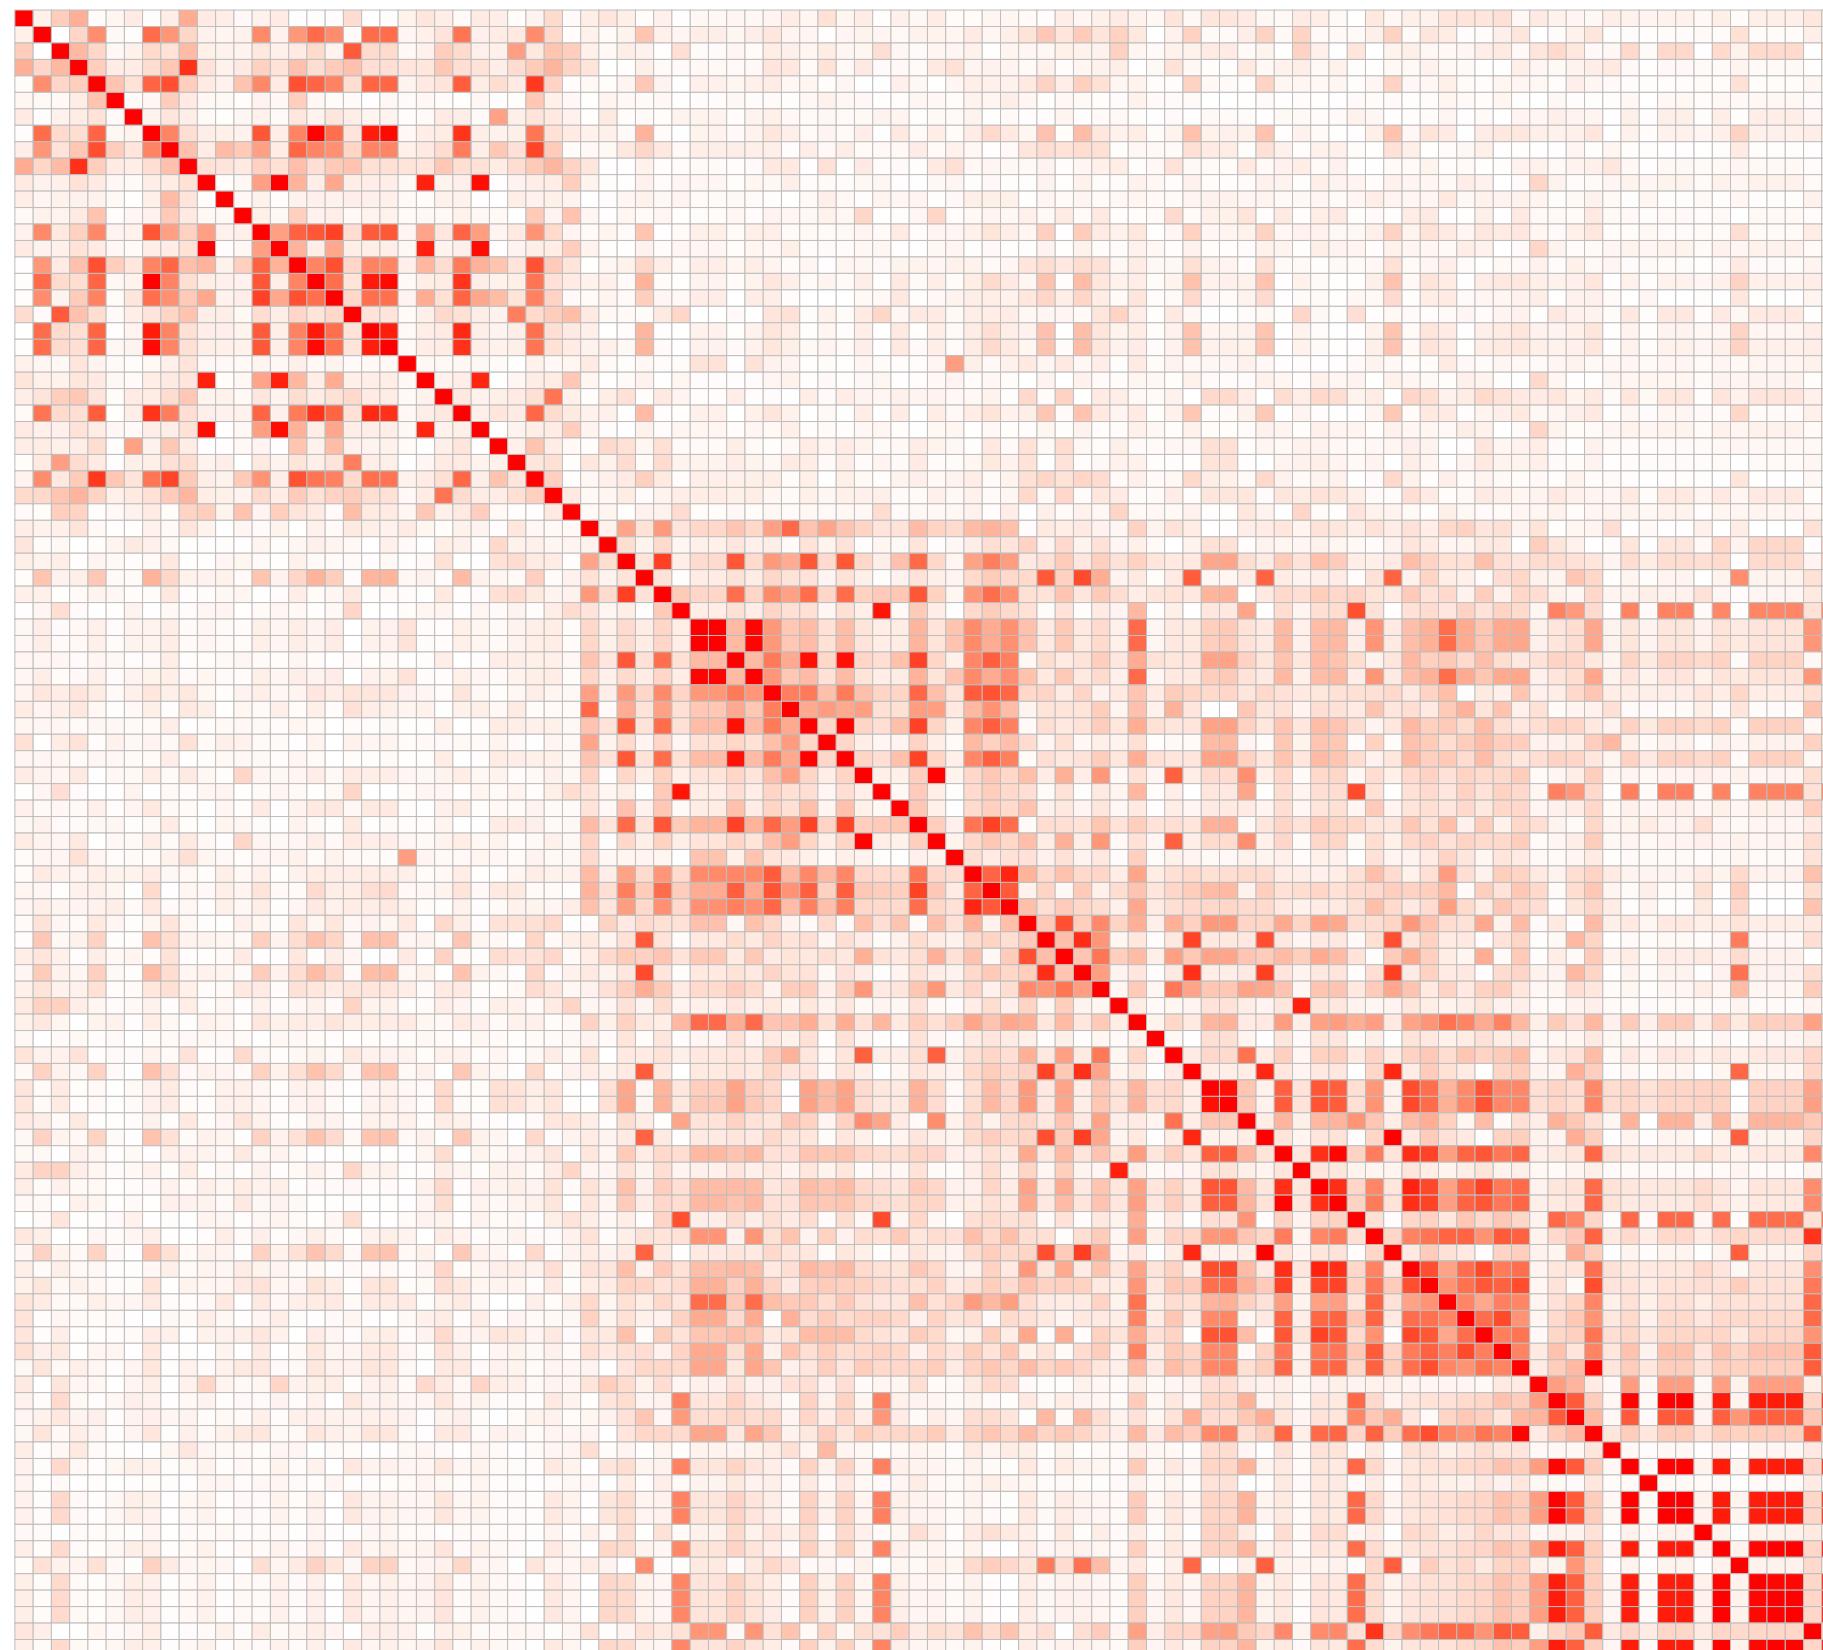

The matrix R captures localized correlation patterns along the genomic axis within a chromosome.

- ▶ LD matrix
- ▶ The results of many, many recombination events

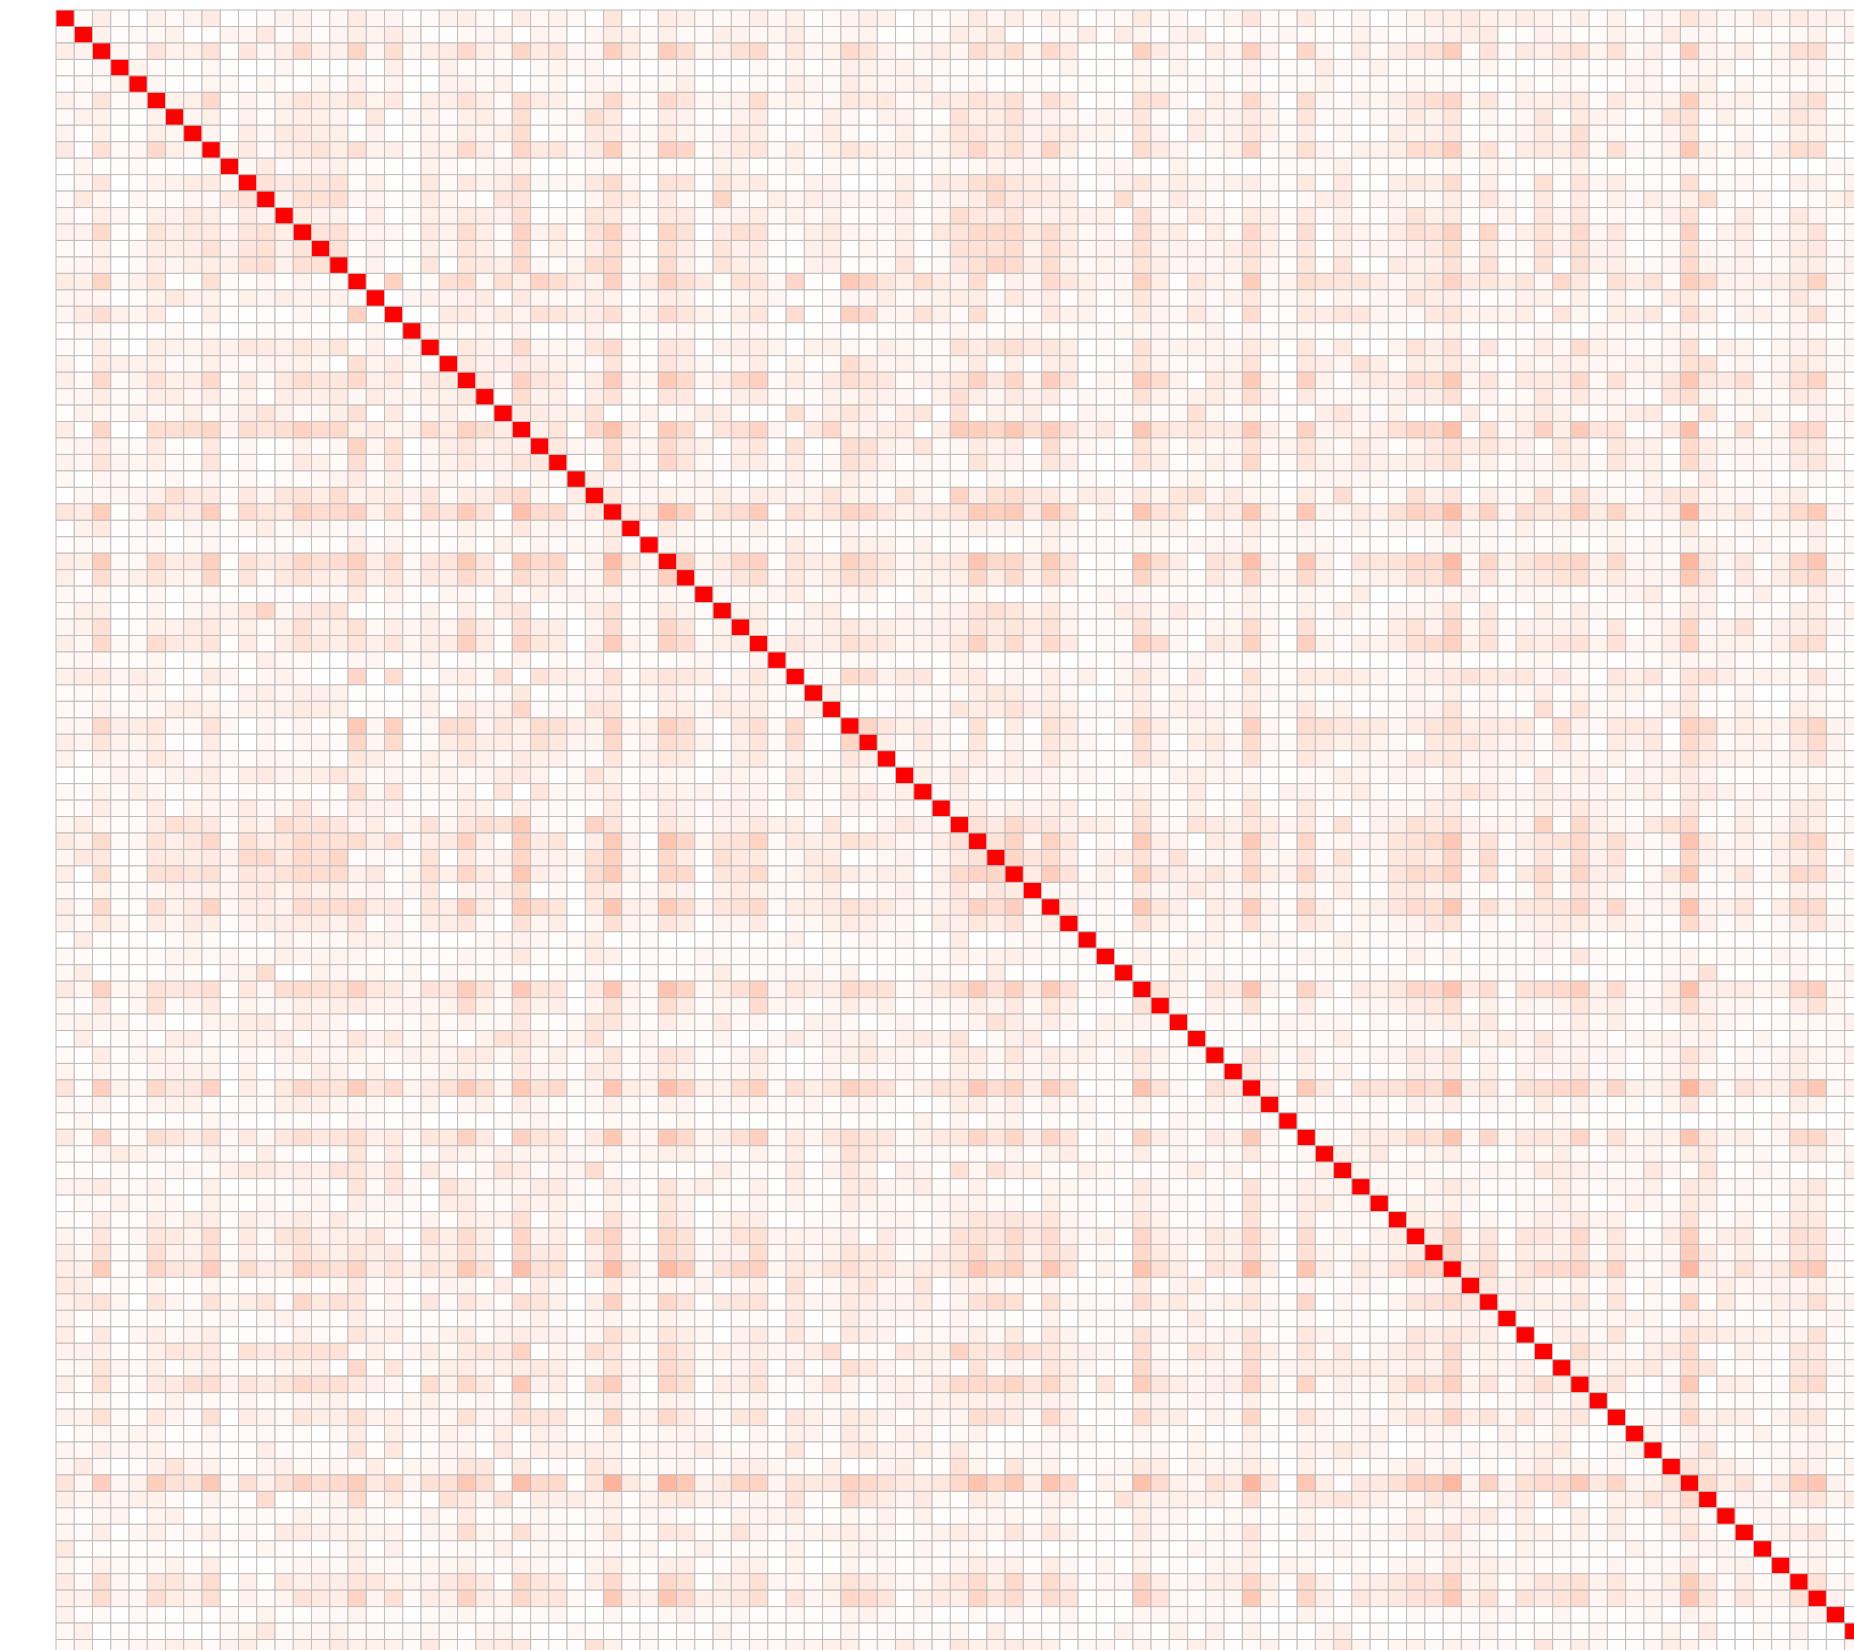

Let's discuss LD structures

Pairwise correlations between SNPs

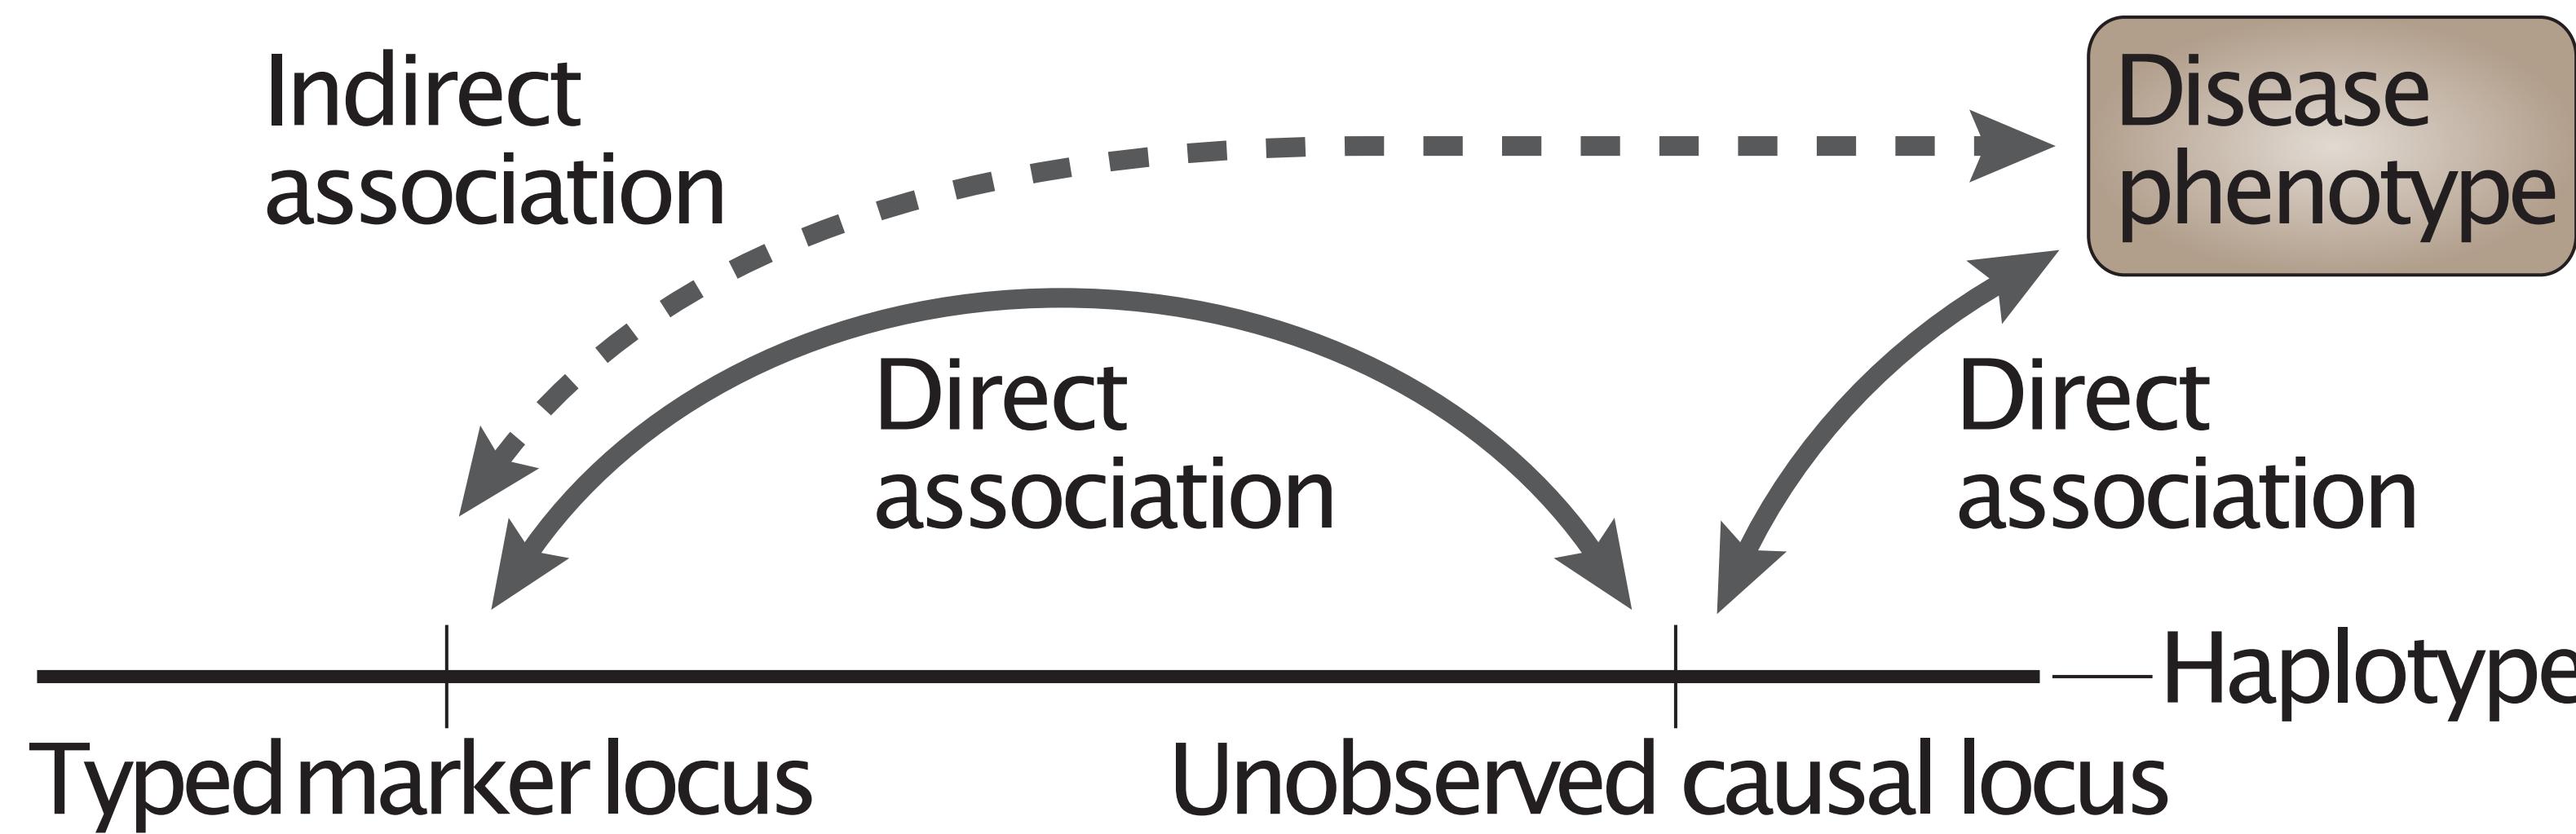

consecutive 100 SNPs

random 100 SNPs

GWAS fail to pinpoint exact locations associated with a disease

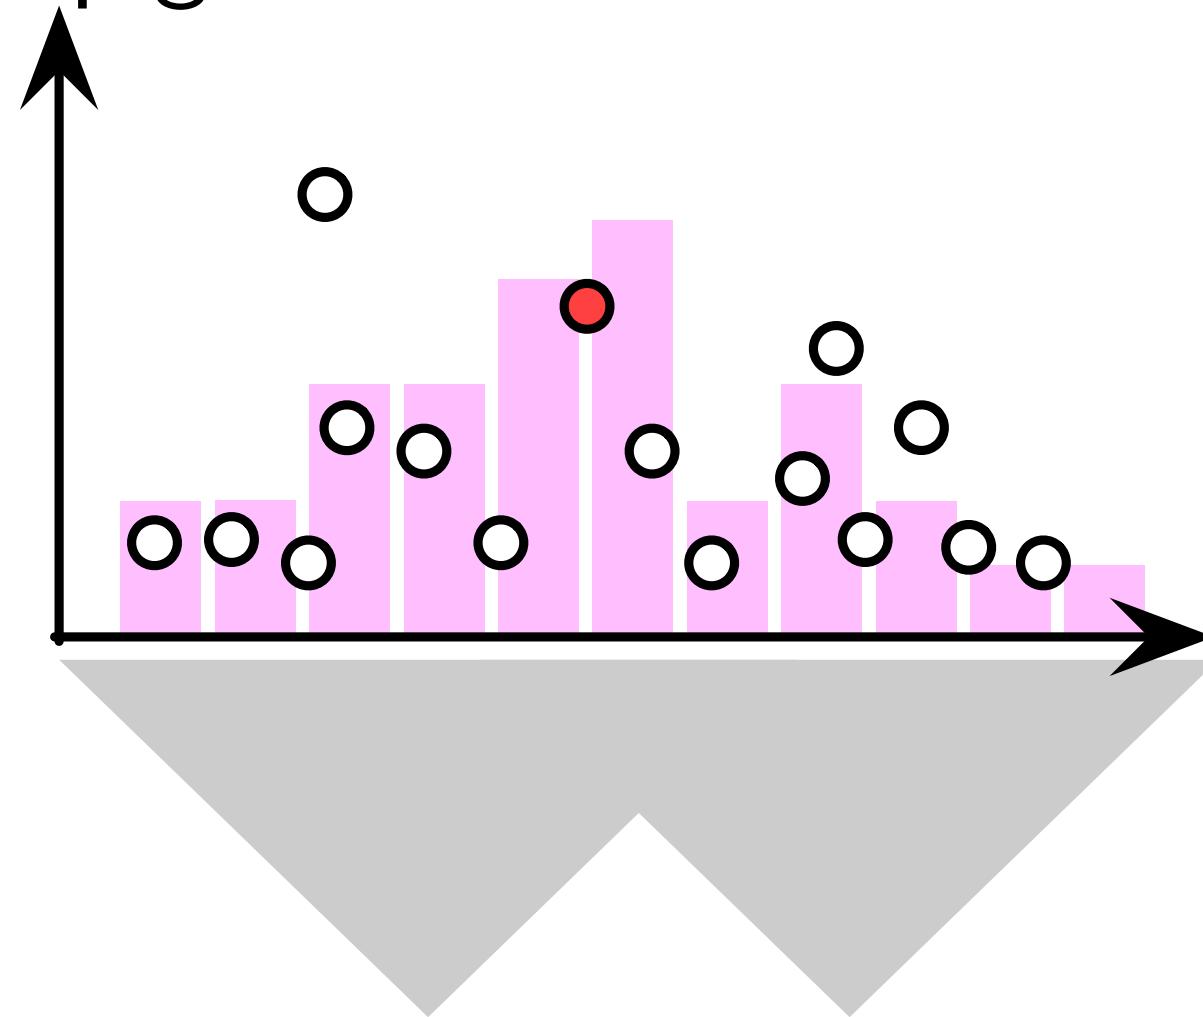

Balding, *Nature Genetics Review* (2006)

Common strategies to deal with LD structures

Strategy 1.

Fine-mapping to find a handful of causal ones

- Bayesian posterior estimation
- Overlap with epigenomics data

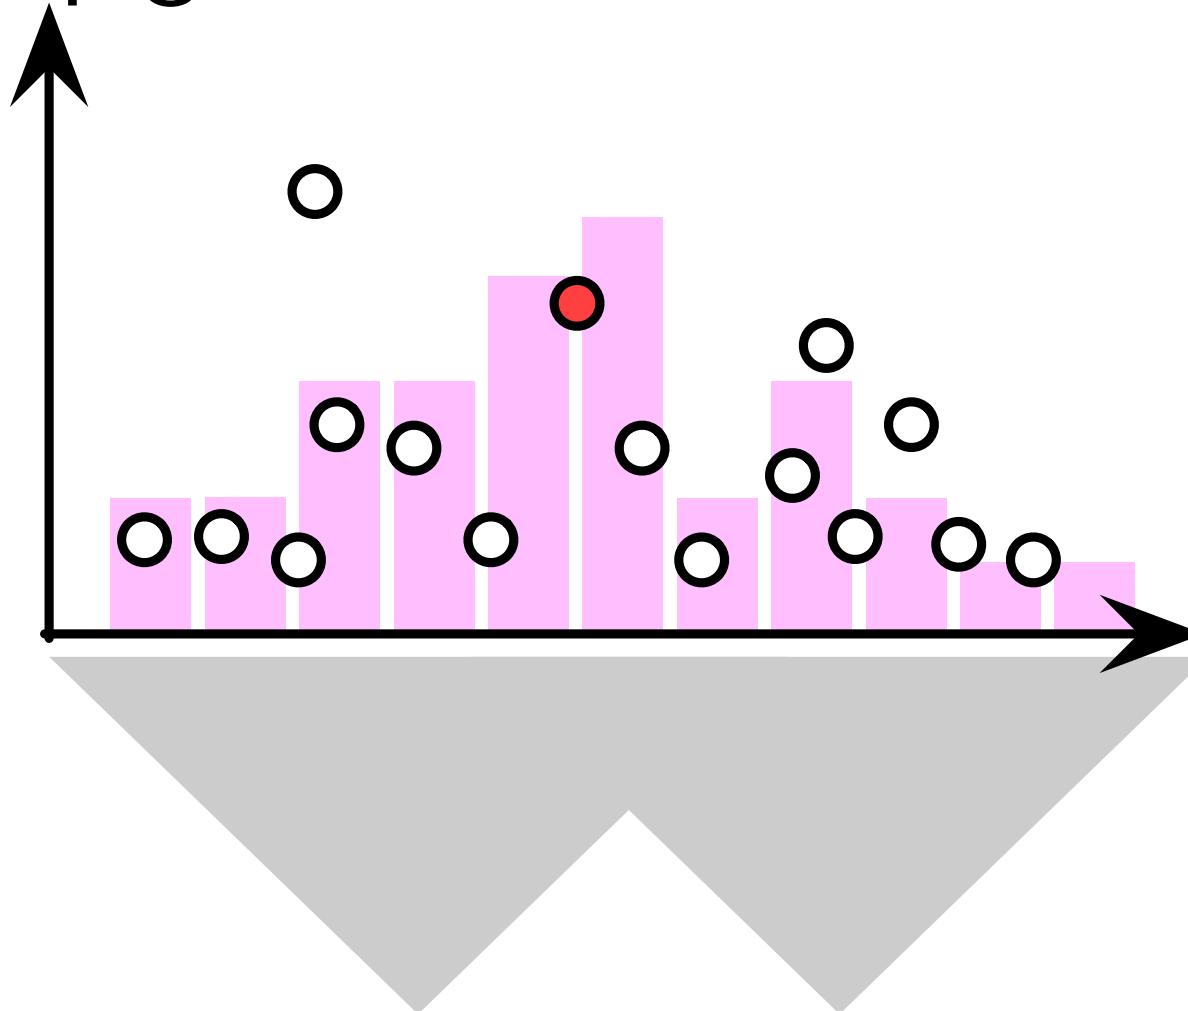

x-axis: genomic location; y-axis: $-\log_{10}$ p-value

Common strategies to deal with LD structures

Strategy 1.

Fine-mapping to find a handful of causal ones

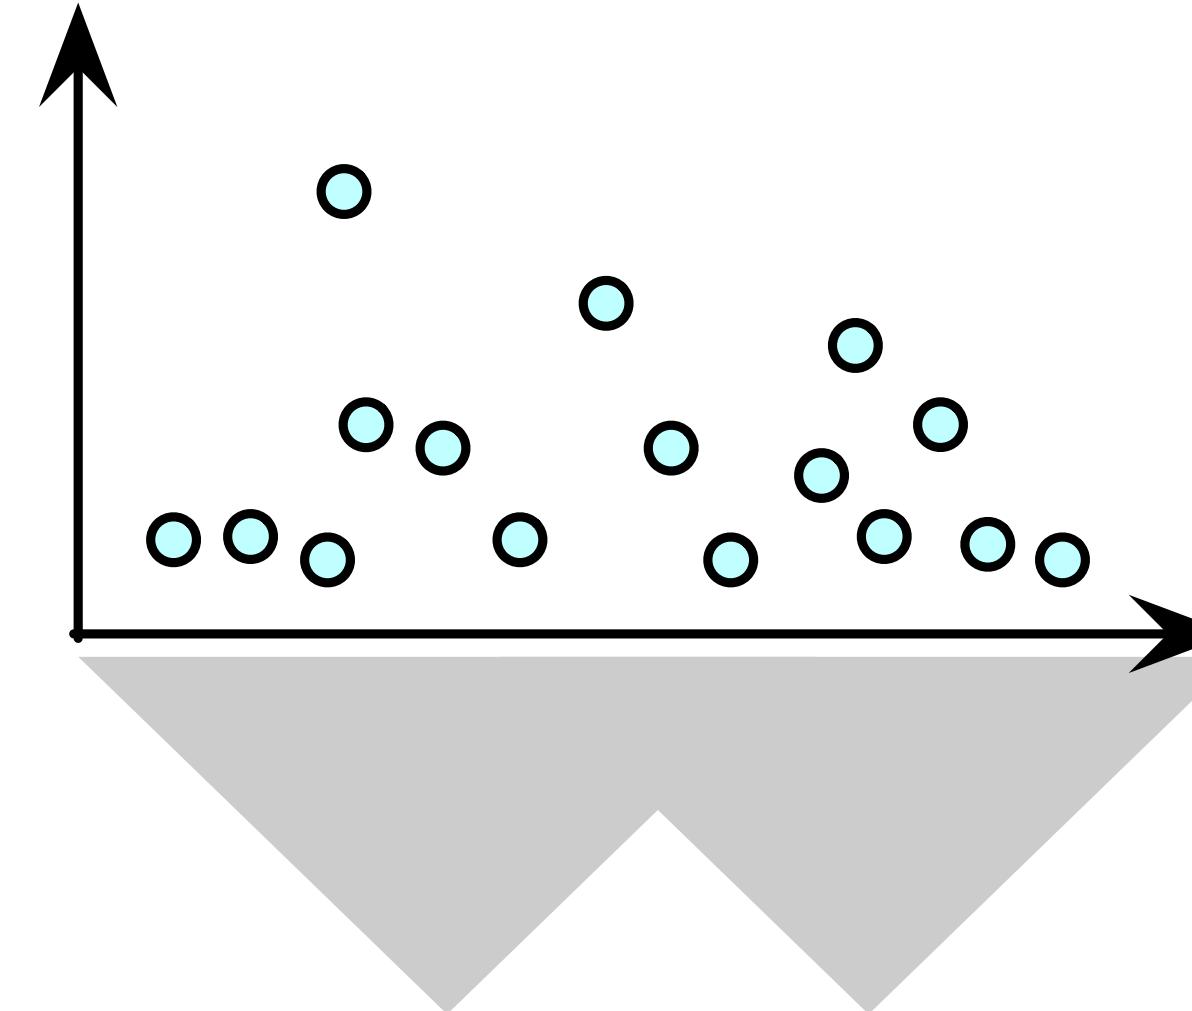

- Bayesian posterior estimation
- Overlap with epigenomics data

Strategy 2.

Aggregation to combine all the information:

- Rare variant analysis
- Gene-level enrichment/association

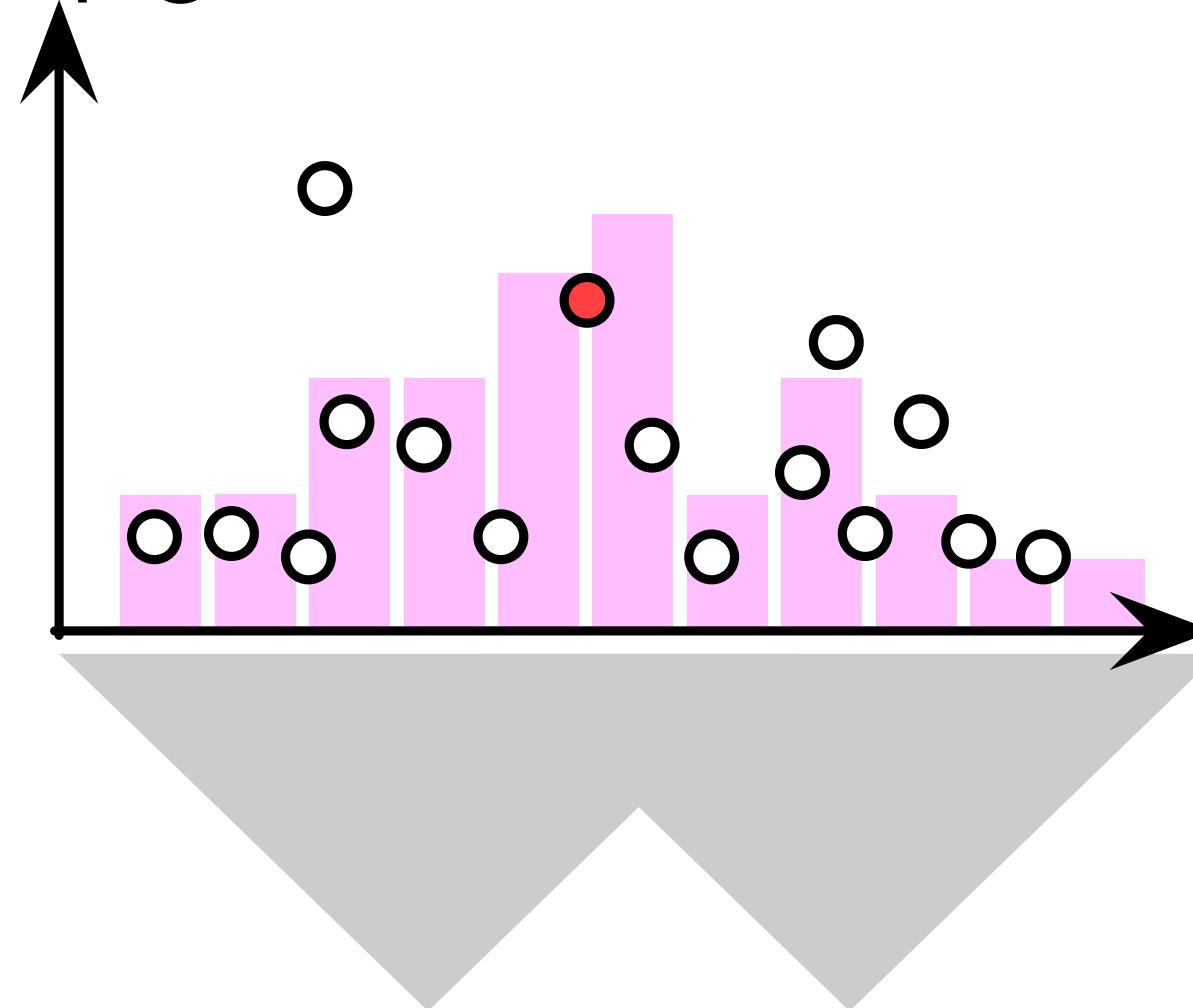

x-axis: genomic location; y-axis: -log10 p-value

Common strategies to deal with LD structures

Strategy 1.

Fine-mapping to find a handful of causal ones

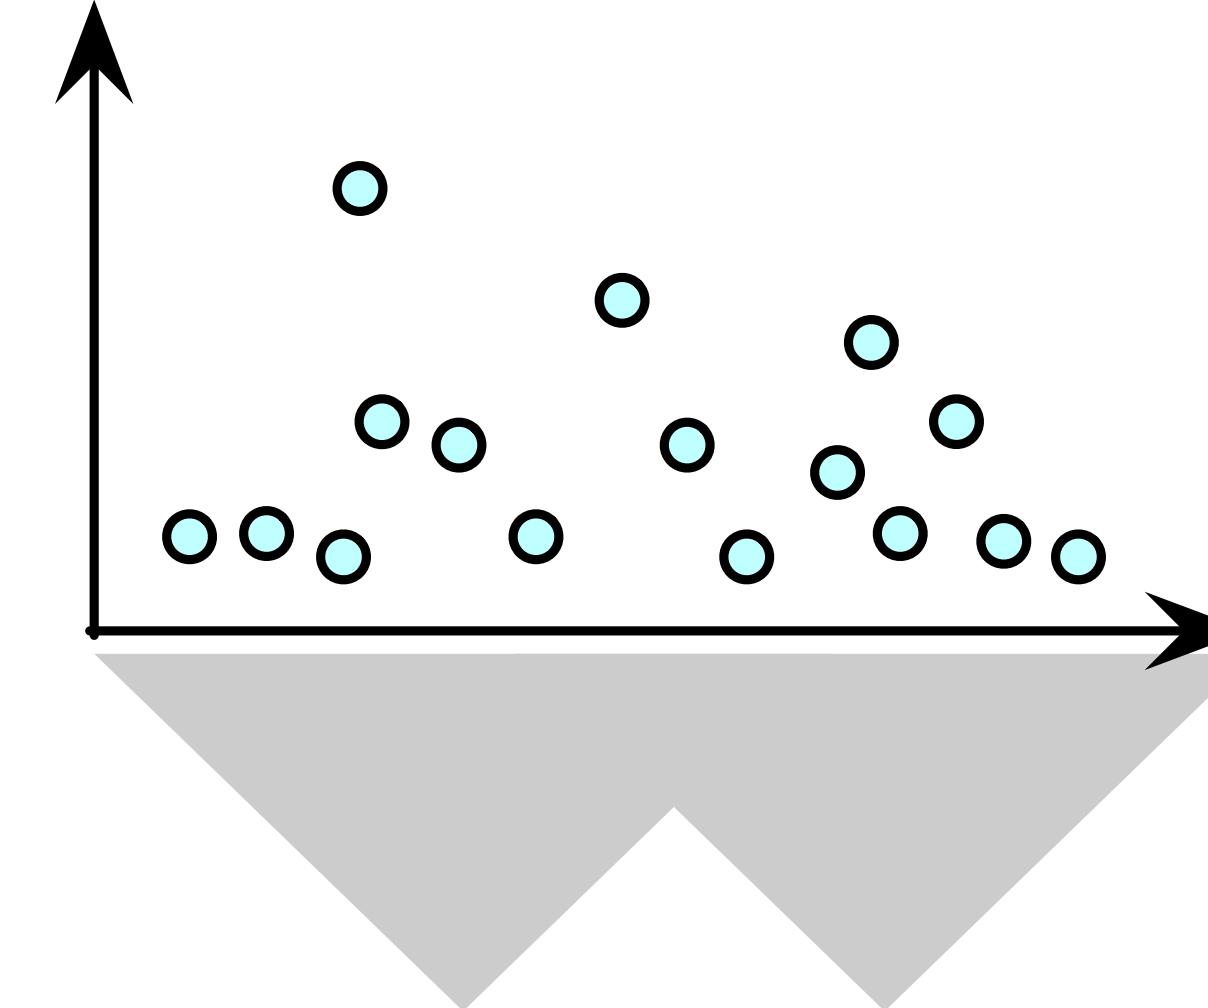

- Bayesian posterior estimation
- Overlap with epigenomics data

Strategy 2.

Aggregation to combine all the information:

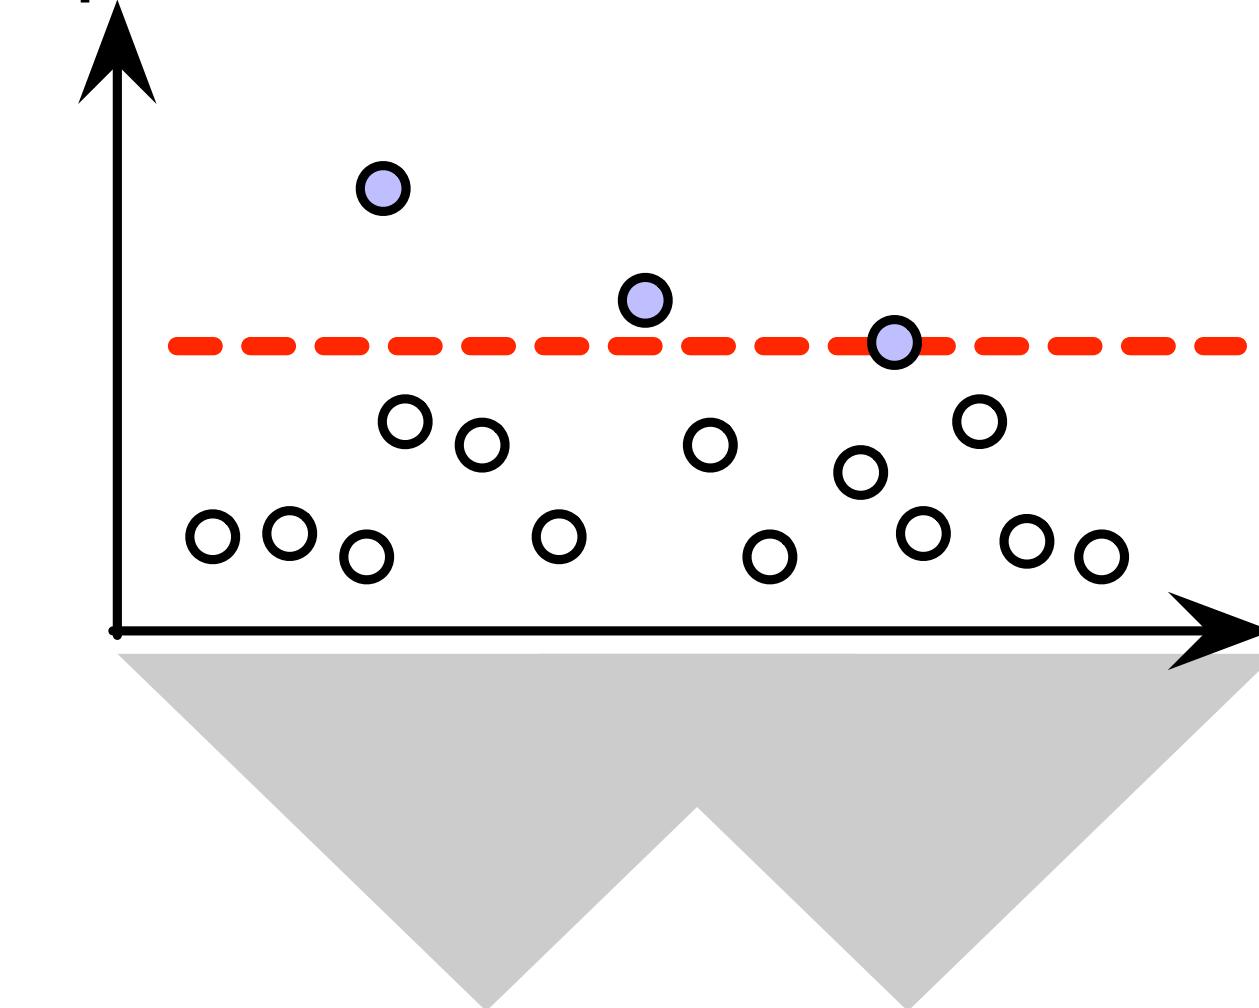

- Rare variant analysis
- Gene-level enrichment/association

Strategy 3. **Pruning** to

remove somewhat redundant information (heuristics)

- p-value thresholding
- Useful in polygenic risk prediction

x-axis: genomic location; y-axis: -log10 p-value

GWAS summary statistics

But we have summary statistics of meta-analysis:

A generative model of SNP-level statistics

For each β_j 's, effect size, variance, z-score:

$$\hat{\beta}_j = \frac{\sum_i X_{ij} Y_i}{\sum_i X_{ij}^2}, \quad \hat{\mathbb{V}}[\beta_j] = \frac{\sigma_\epsilon^2}{\sum_{i=1} X_{ij}^2}, \quad Z_j = \frac{\hat{\beta}_j}{\sqrt{\hat{\mathbb{V}}[\beta_j]}}$$

GWAS summary statistics

But we have summary statistics of meta-analysis:

A generative model of SNP-level statistics

For each β_j 's, effect size, variance, z-score:

$$\hat{\beta}_j = \frac{\sum_i X_{ij} Y_i}{\sum_i X_{ij}^2}, \quad \hat{\mathbb{V}}[\beta_j] = \frac{\sigma_\epsilon^2}{\sum_{i=1} X_{ij}^2}, \quad Z_j = \frac{\hat{\beta}_j}{\sqrt{\hat{\mathbb{V}}[\beta_j]}}$$

Although **the underlying multivariate regression model**:

$$\mathbf{y} = \mathbf{X}\boldsymbol{\theta} + \boldsymbol{\epsilon}$$

where $\boldsymbol{\theta}_j \neq \beta_j$

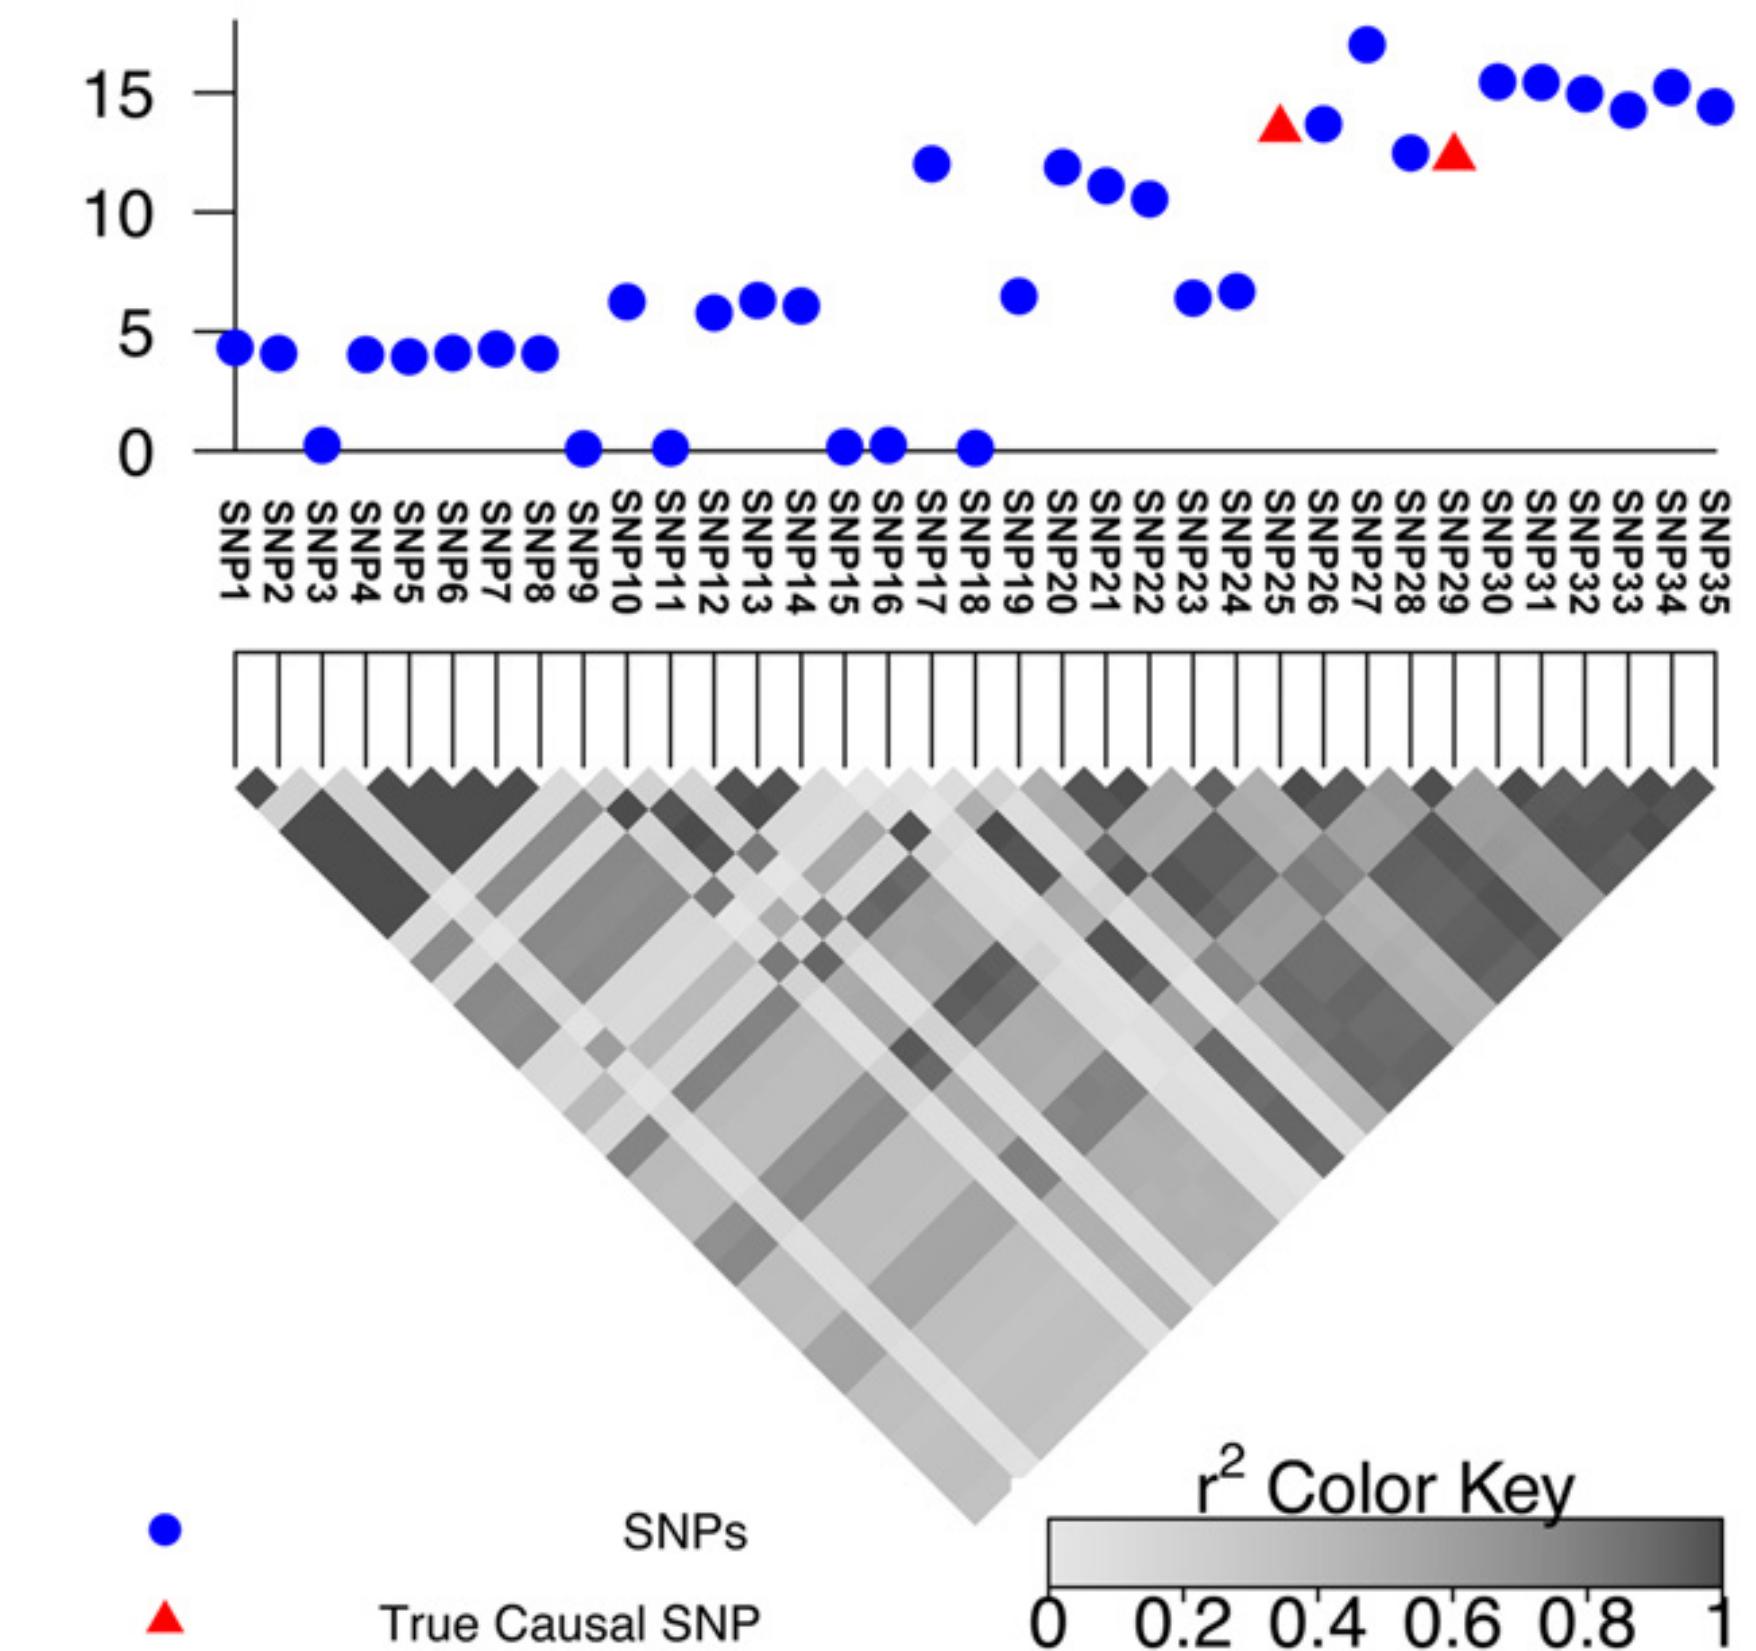

What is the relationship between the summary (univariate) and multivariate effects?

For simplicity, let's assume standardized genotype matrix X , i.e., $\bar{X}_j = 0$ and $\hat{\sigma}_{X_j}^2 = 1$.

Then we have z-score

$$\hat{Z}_j = \sum_{i=1}^n X_{ij} Y_i / \sigma_\epsilon \sqrt{n}$$

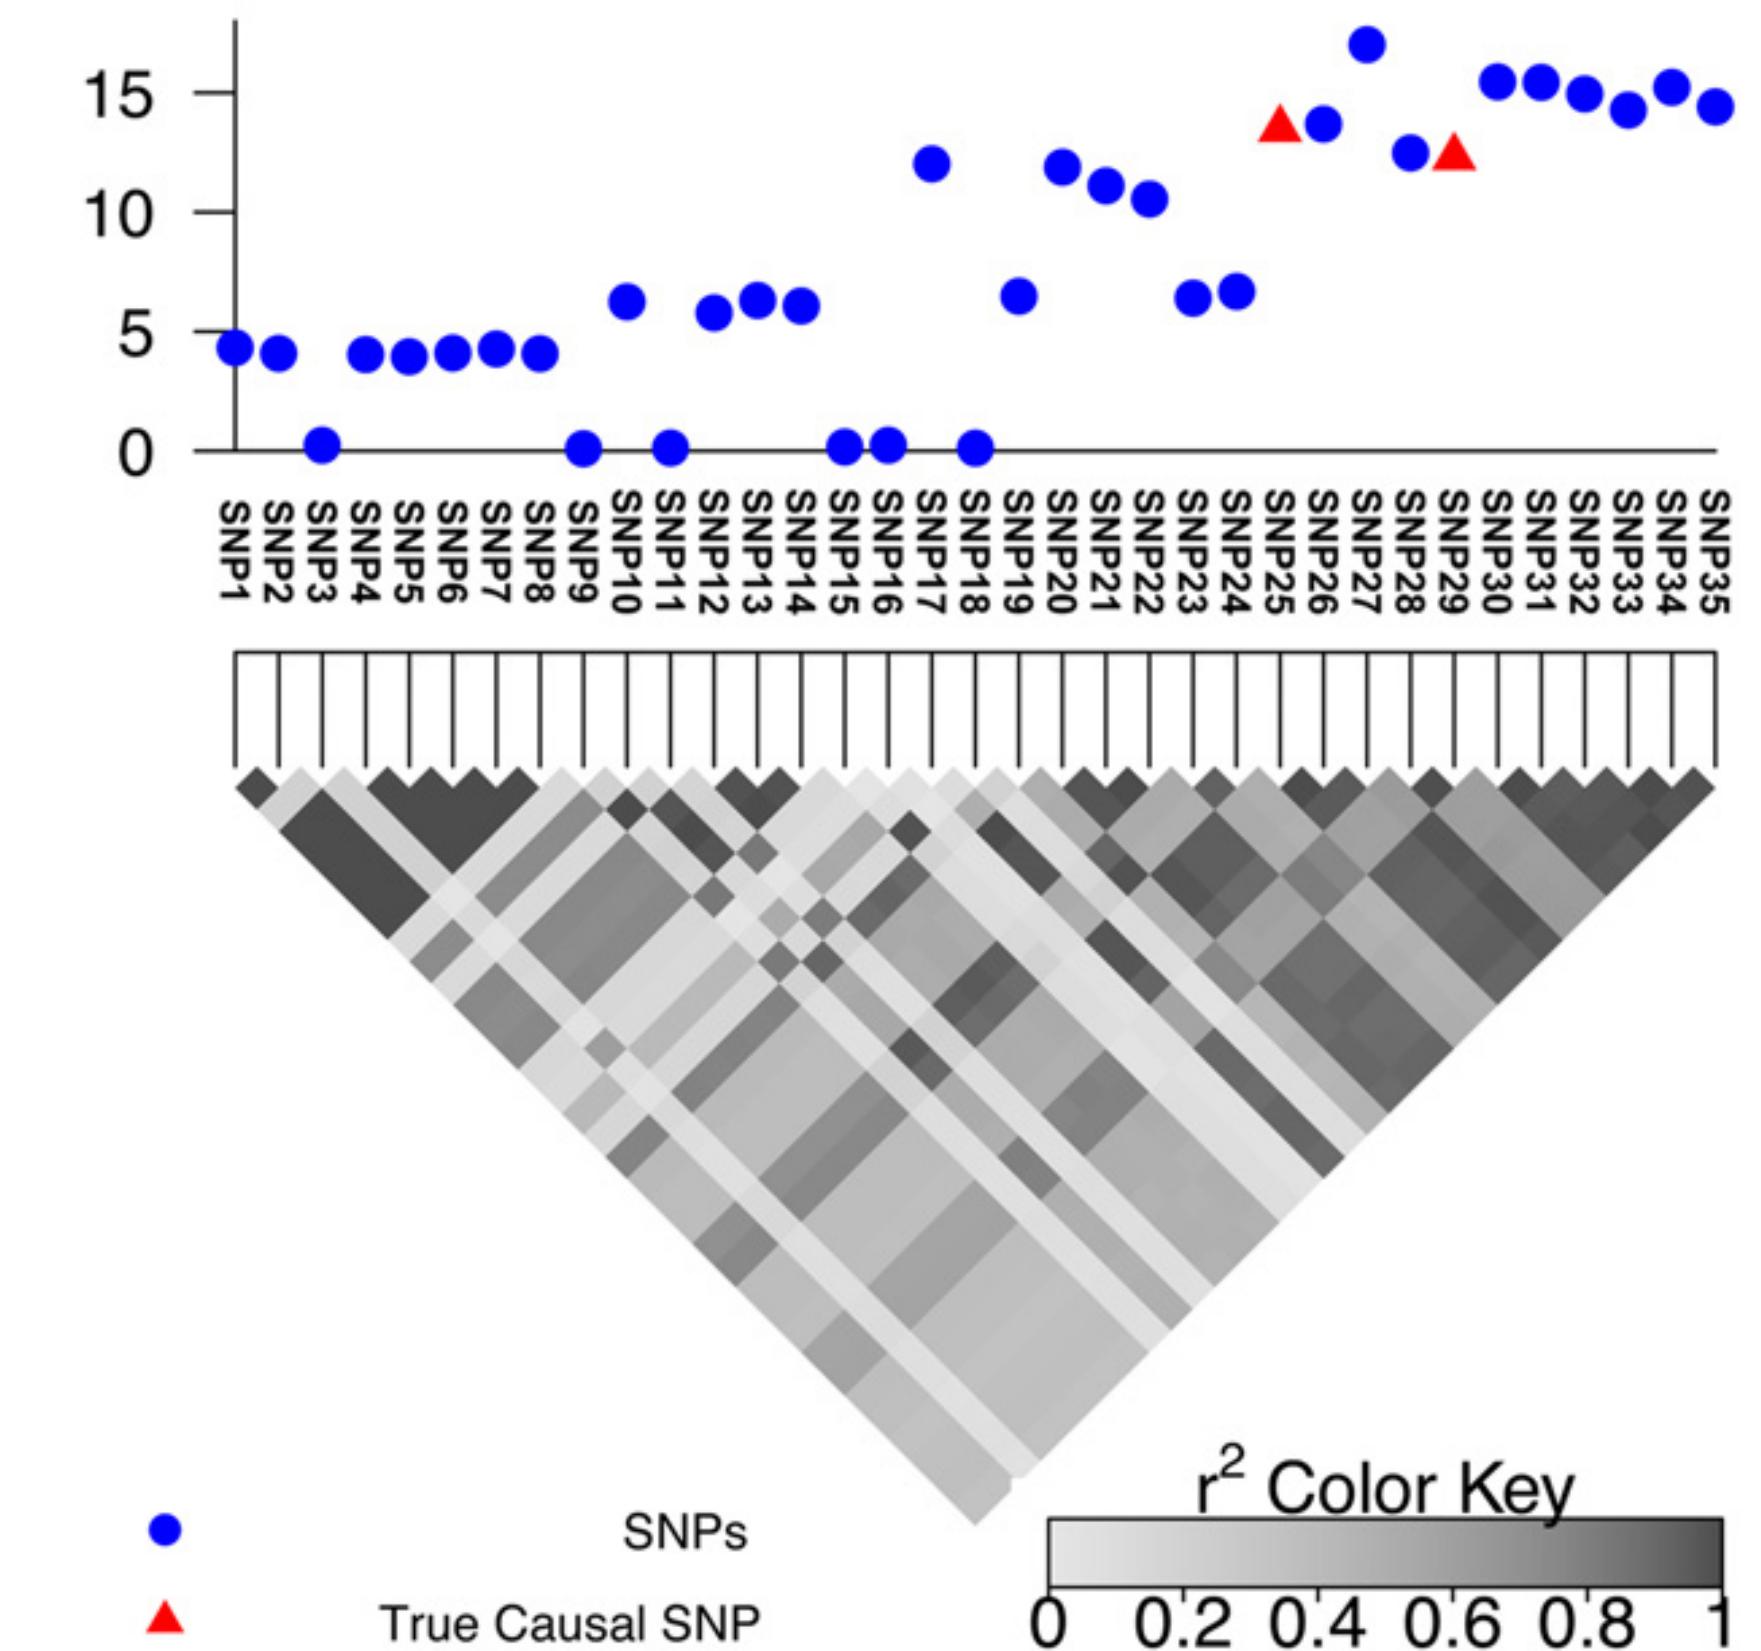

for all $j \in [p]$.

What is the relationship between the summary (univariate) and multivariate effects?

For simplicity, let's assume standardized genotype matrix X , i.e., $\bar{X}_j = 0$ and $\hat{\sigma}_{X_j}^2 = 1$.
Then we have z-score

$$\begin{matrix} \text{Z} \\ p \times 1 \text{ univariate} \end{matrix} = \frac{1}{\sigma \sqrt{n}} X^\top \mathbf{y}$$

Hormozdiari *et al.*, Genetics (2014); Zhu and Stephens, Annals of Applied Statistics (2017)

What is the relationship between the summary (univariate) and multivariate effects?

For simplicity, let's assume standardized genotype matrix X , i.e., $\bar{X}_j = 0$ and $\hat{\sigma}_{X_j}^2 = 1$.
Then we have z-score

$$\begin{array}{c} \mathbf{z} \\ p \times 1 \text{ univariate} \end{array} = \frac{1}{\sigma\sqrt{n}} X^\top \mathbf{y} = \frac{1}{\sigma\sqrt{n}} X^\top \underbrace{(X\theta + \epsilon)}_{\text{a multivariate model}}$$

Hormozdiari *et al.*, Genetics (2014); Zhu and Stephens, Annals of Applied Statistics (2017)

What is the relationship between the summary (univariate) and multivariate effects?

For simplicity, let's assume standardized genotype matrix X , i.e., $\bar{X}_j = 0$ and $\hat{\sigma}_{X_j}^2 = 1$.
Then we have z-score

$$\begin{aligned} \text{z} &= \frac{1}{\sigma\sqrt{n}} X^\top y = \frac{1}{\sigma\sqrt{n}} X^\top \underbrace{(X\theta + \epsilon)}_{\text{a multivariate model}} \\ &= \frac{\sqrt{n}}{\sigma} \underbrace{\left(\frac{1}{n} X^\top X \right)}_{\text{LD}} \theta + \frac{1}{\sigma\sqrt{n}} X^\top \epsilon \end{aligned}$$

What is the relationship between the summary (univariate) and multivariate effects?

For simplicity, let's assume standardized genotype matrix X , i.e., $\bar{X}_j = 0$ and $\hat{\sigma}_{X_j}^2 = 1$.
Then we have z-score

$$\begin{aligned} \text{z} &= \frac{1}{\sigma\sqrt{n}} X^\top \mathbf{y} = \frac{1}{\sigma\sqrt{n}} X^\top \underbrace{(X\theta + \epsilon)}_{\text{a multivariate model}} \\ &= \mathbf{R} \frac{\sqrt{n}}{\sigma} \theta + \tilde{\epsilon}, \quad \tilde{\epsilon} \sim \mathcal{N}(0, \mathbf{R}) \end{aligned}$$

where $\mathbf{R} = n^{-1} X^\top X$ is an empirical LD matrix.

Hormozdiari *et al.*, Genetics (2014); Zhu and Stephens, Annals of Applied Statistics (2017)

How can GWAS p-value fool human genetics research?

Some thought experiment on causal variant i . We generated y as follows:

$$\mathbf{y} = \mathbf{x}_i \theta_i + \dots$$

Because of LD and population structure, we have

$$\mathbf{x}_j = \mathbf{u} + \tilde{\mathbf{x}}_j \dots, \mathbb{E}[\mathbf{x}_i^\top \tilde{\mathbf{x}}_j] = n\delta$$

This structural bias and correlation will simply remain in a z-score:

$$z_j = n^{-1/2} \mathbf{x}_j^\top \mathbf{y} = n^{-1/2} (\mathbf{u} + \tilde{\mathbf{x}}_j + \dots)^\top (\mathbf{x}_i \theta_i + \dots)$$

How can GWAS p-value fool human genetics research?

Some thought experiment on causal variant i . We generated y as follows:

$$\mathbf{y} = \mathbf{x}_i \theta_i + \dots$$

Because of LD and population structure, we have

$$\mathbf{x}_j = \mathbf{u} + \tilde{\mathbf{x}}_j \dots, \mathbb{E}[\mathbf{x}_i^\top \tilde{\mathbf{x}}_j] = n\delta$$

This structural bias and correlation will simply remain in a z-score:

$$z_j = \frac{\mathbf{u}^\top \mathbf{x}_i}{n^{1/2}} \theta_i + \underbrace{\frac{\mathbf{x}_i^\top \tilde{\mathbf{x}}_j}{n^{1/2}} \theta_i}_{\text{population structure}} + \underbrace{\delta n^{1/2}}_{\text{tight LD between } i,j} \theta_i$$

How can GWAS p-value fool human genetics research?

Some thought experiment on causal variant i . We generated y as follows:

$$\mathbf{y} = \mathbf{x}_i \theta_i + \dots$$

Because of LD and population structure, we have

$$\mathbf{x}_j = \mathbf{u} + \tilde{\mathbf{x}}_j \dots, \mathbb{E}[\mathbf{x}_i^\top \tilde{\mathbf{x}}_j] = n\delta$$

This structural bias and correlation will simply remain in a z-score:

- ▶ Population structure-bias will diminish as $n \rightarrow \infty$
- ▶ LD-bias will aggravate as $n \rightarrow \infty$

Polygenic regression model

- ▶ An “infinitesimal” (aka omnigenic) model: Every variant contributes to total heritability in complex traits.
- ▶ First coined by R.A. Fisher, trying to reconcile between Biometricians’ and Medelians’ different points of view.
- ▶ Pea (Mendelian) vs. height (biometrician)

Let's simulate GWAS data

```
set.seed(47)
xtot <- apply(X, 2, scale)

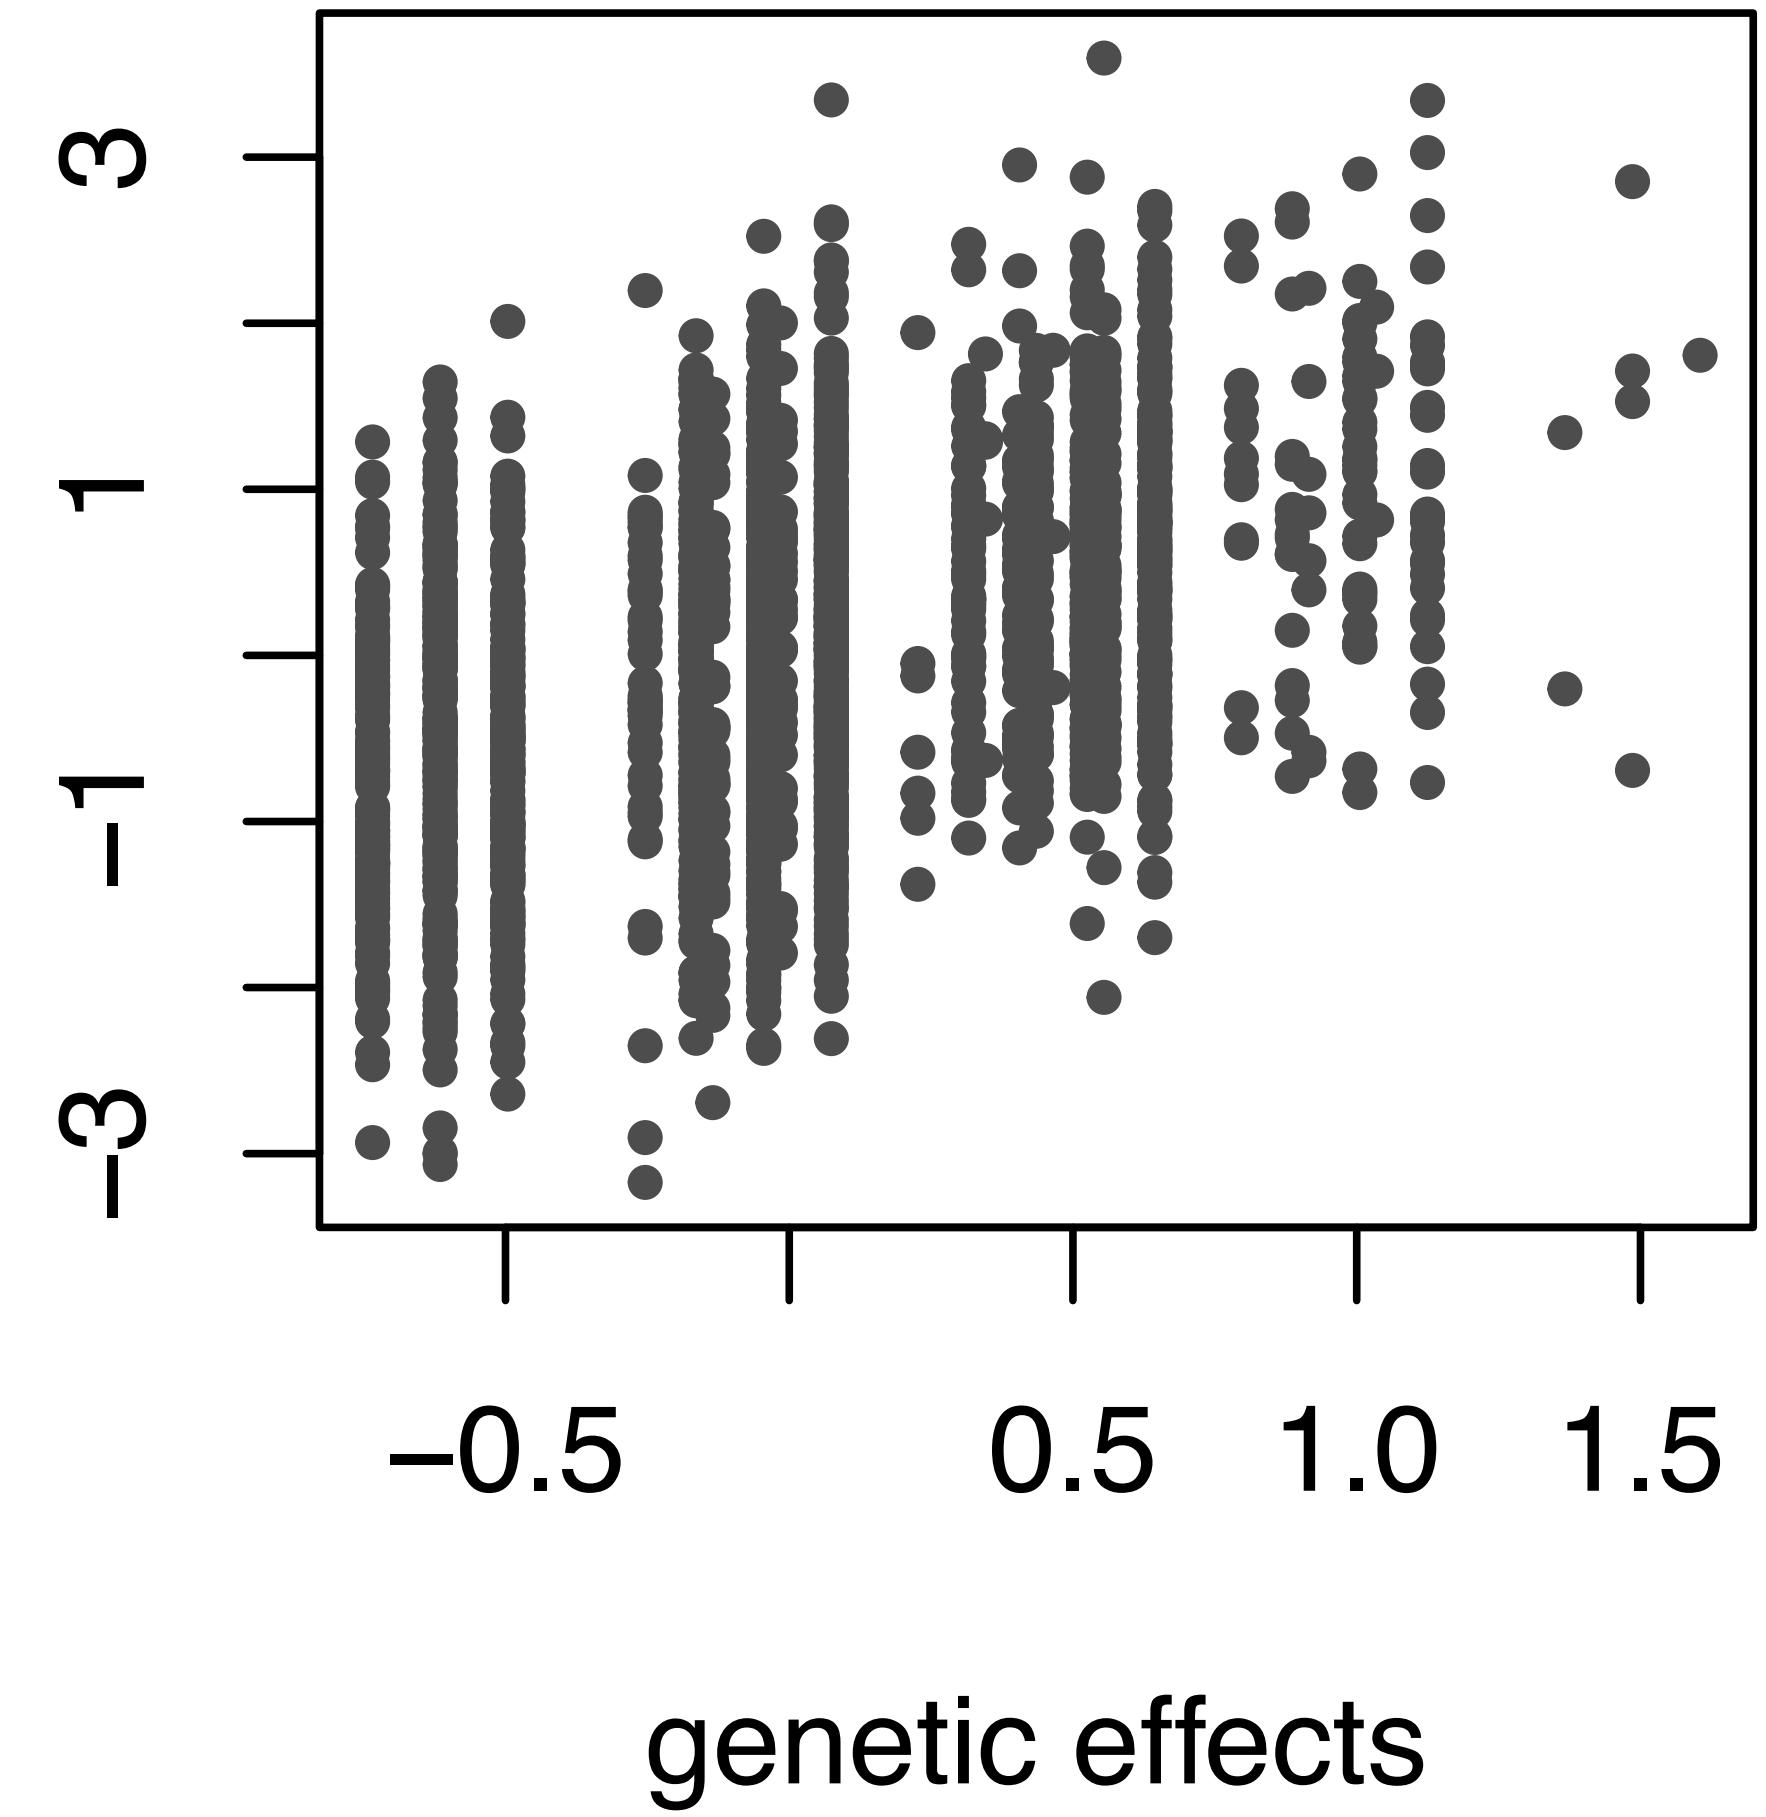

## just remove missing values
xtot[is.na(xtot)] <- 0

## random subset 300
rr <- sample(nrow(xtot), 300)
xx <- xtot[-rr, , drop=F]

sim <- simulate.pgs(xx, 0.2, 3)
y <- sim$y
```

$$y = \sum_{j \in \text{causal}} x_j \beta_j + \epsilon$$

phenotypes

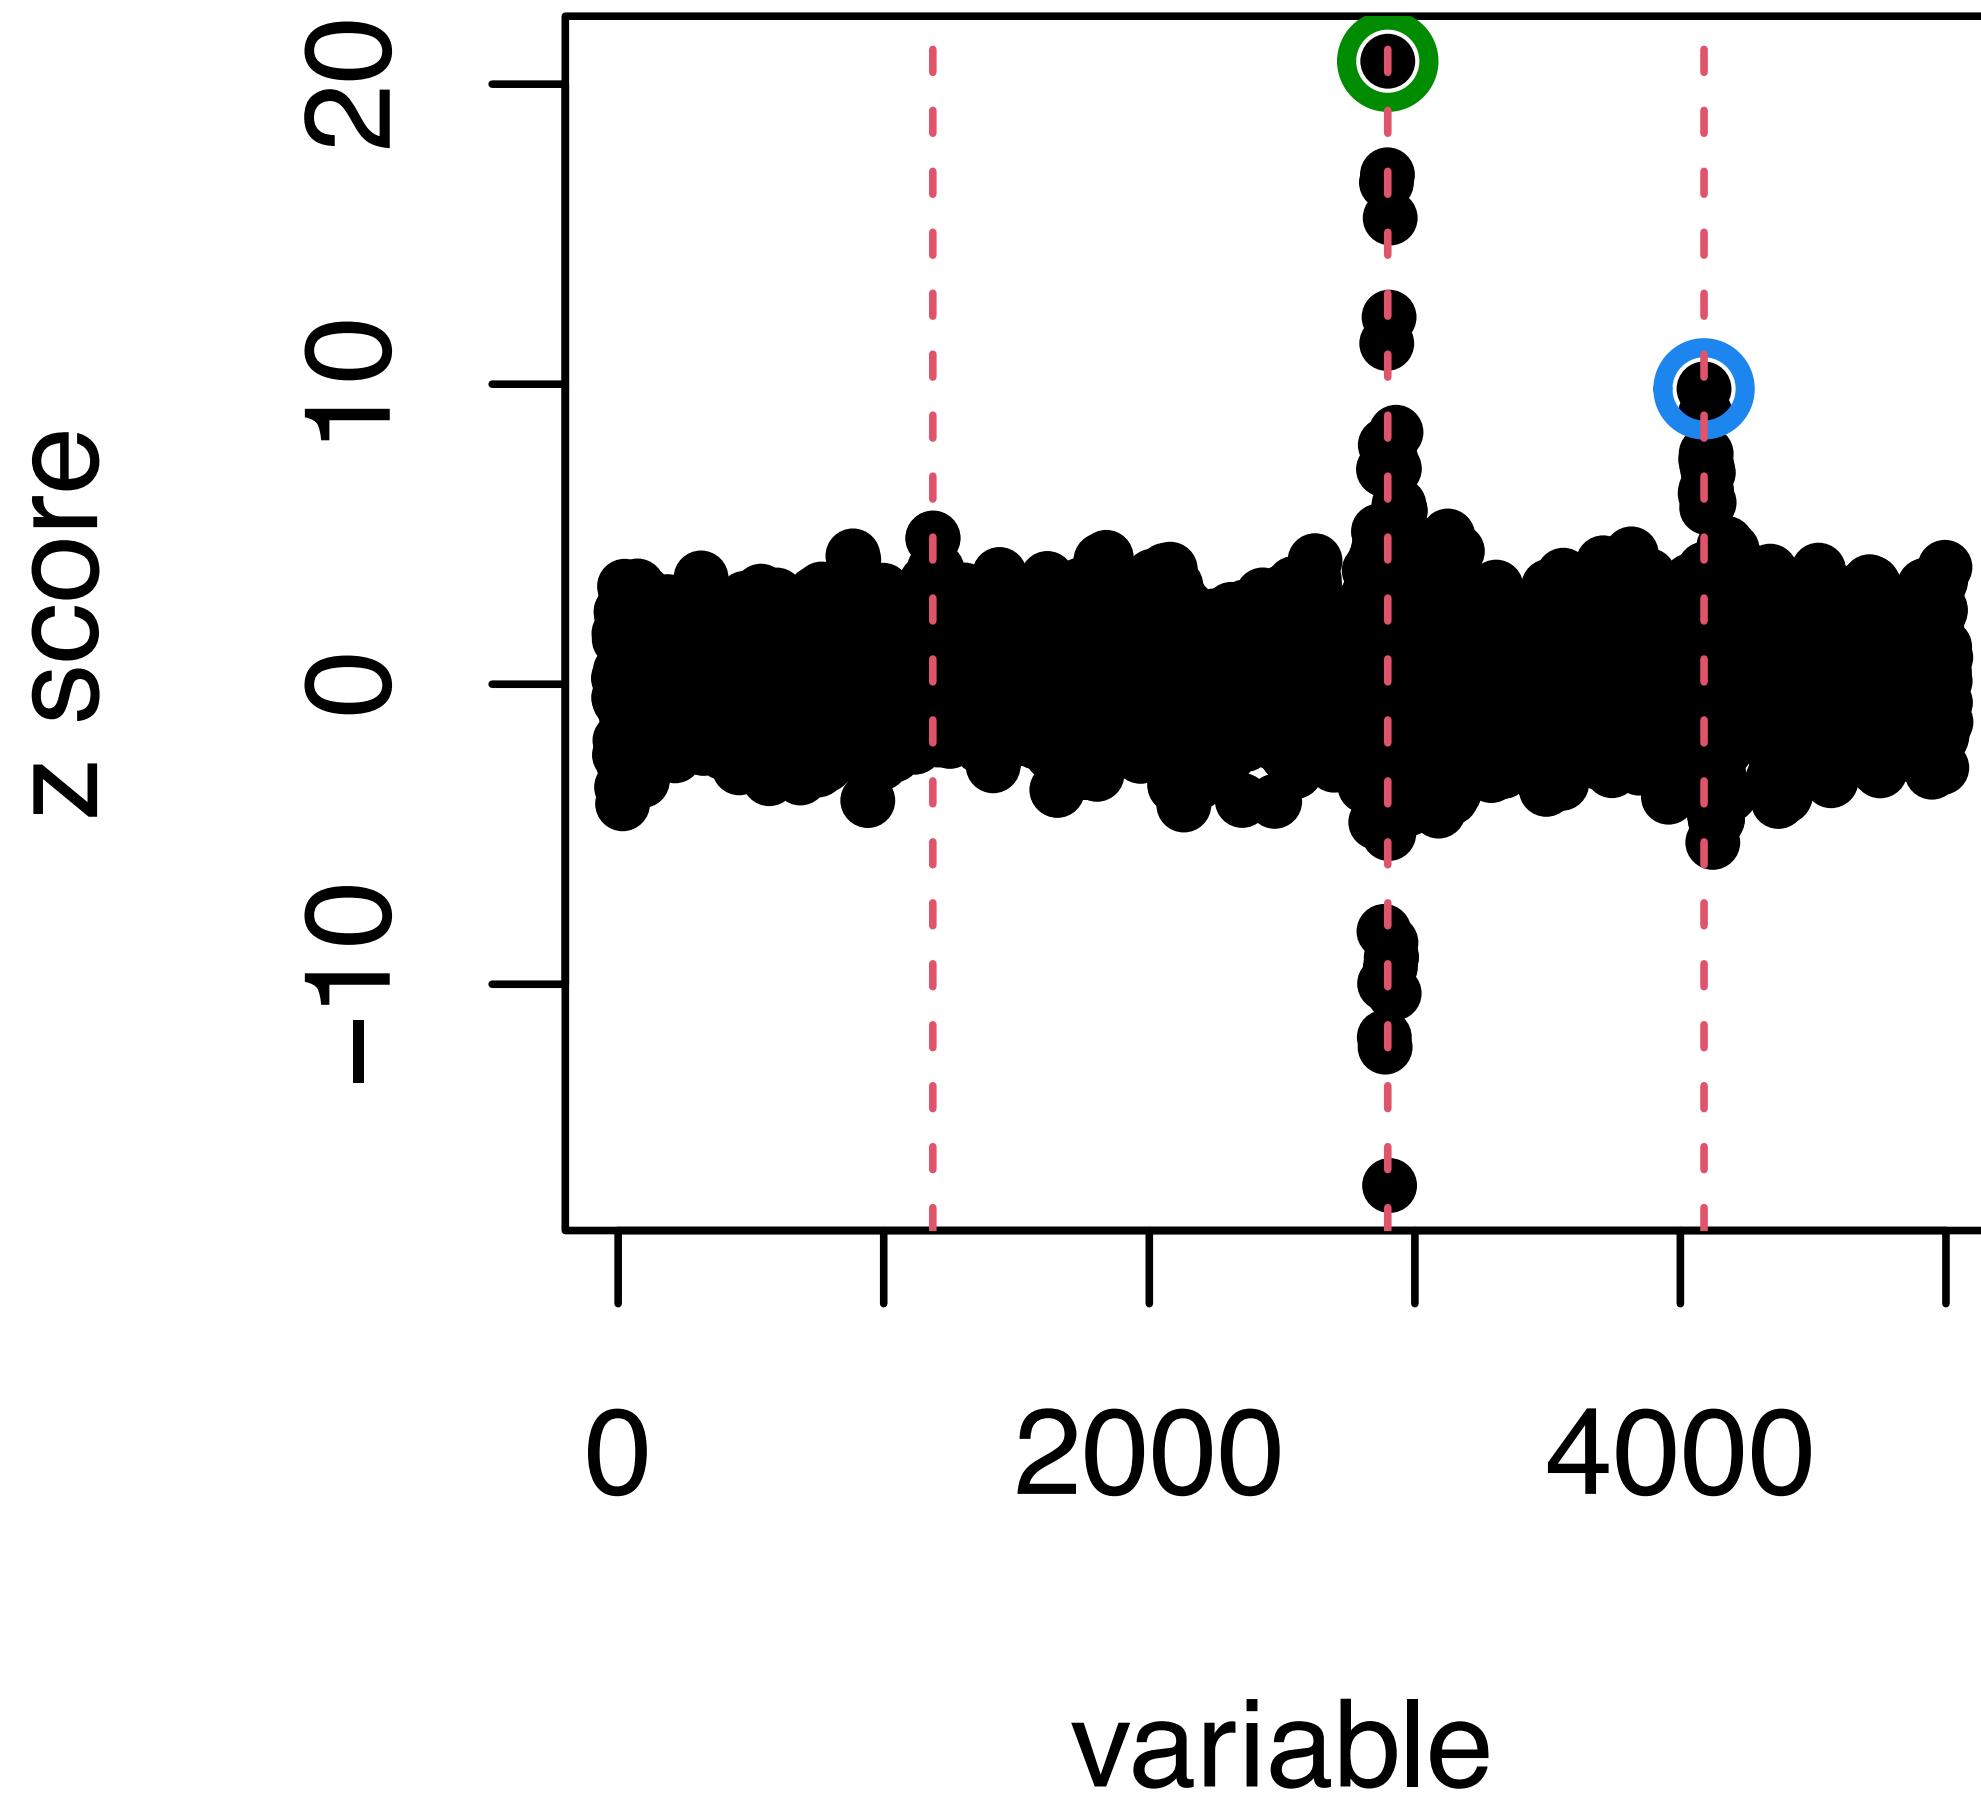

Run SuSiE to identify causal variants

```
library(susieR)

susie.full <-
  susie(xx, y, L = 30,
compute_univariate_zscore=TRUE)
```

- ▶ $2190 \times 5000 X$ genotype
- ▶ $2190 \times 1 y$ response
- ▶ Dashed lines: causal variants

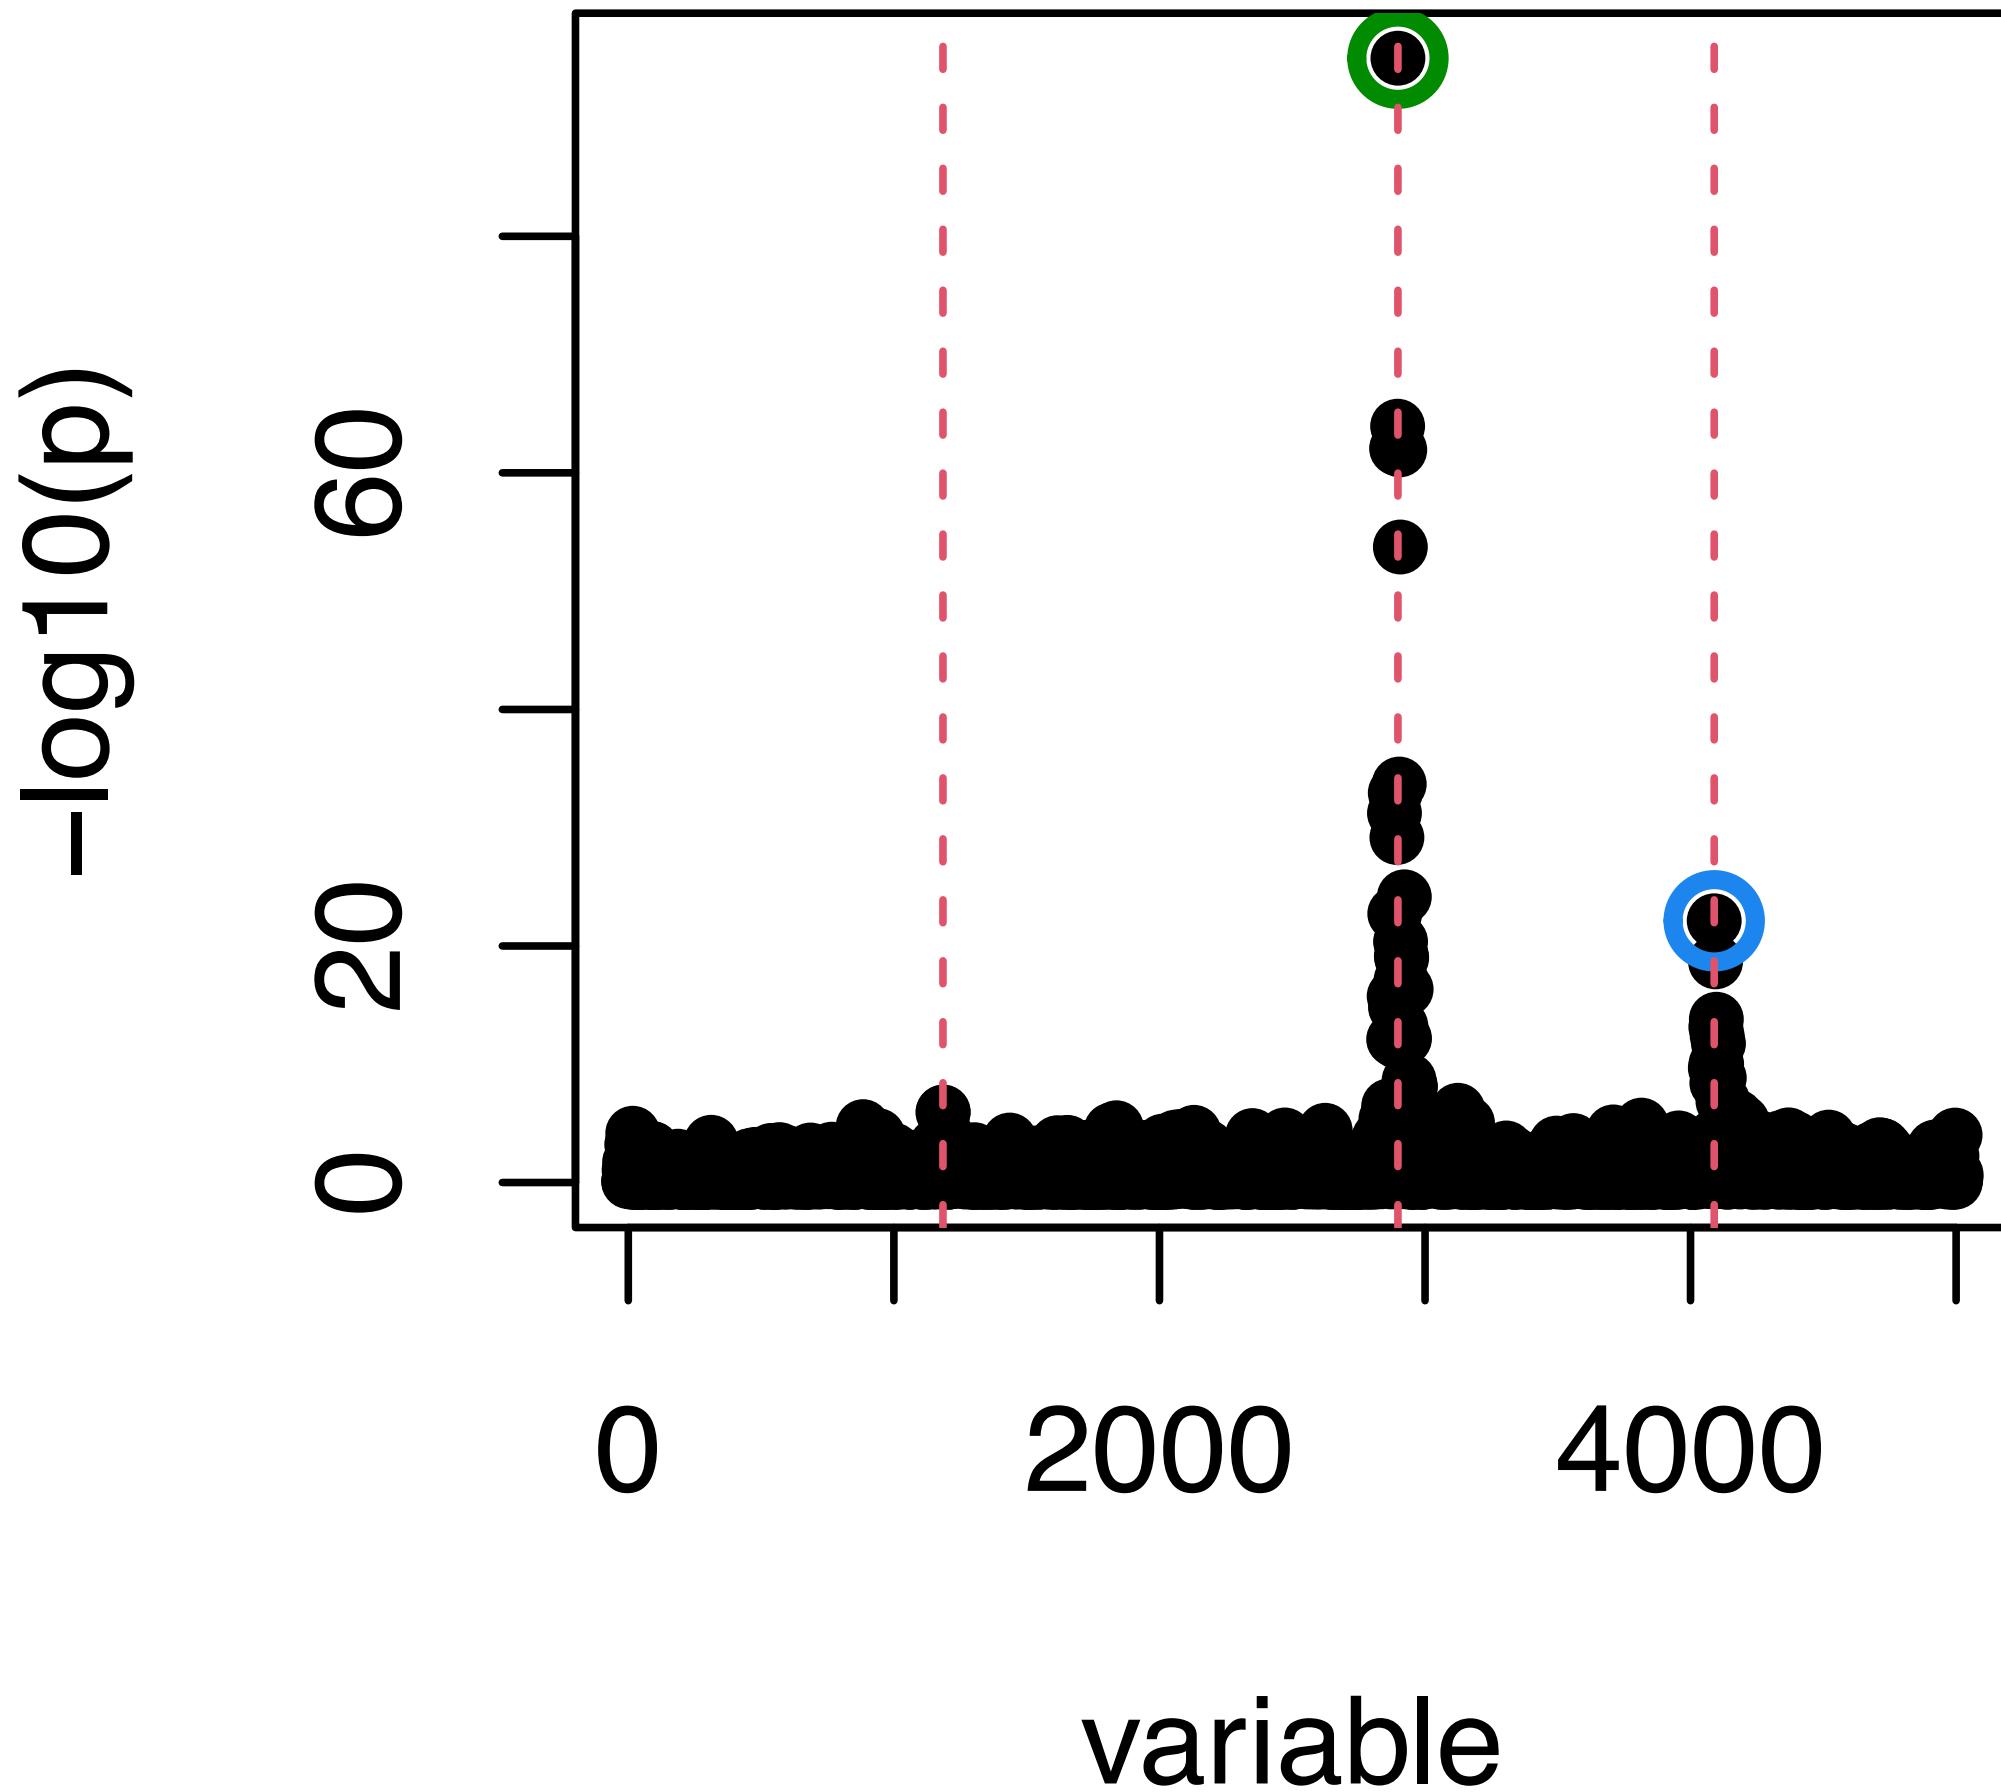

Run SuSiE to identify causal variants

```
library(susieR)

susie.full <-
  susie(xx, y, L = 30,
compute_univariate_zscore=TRUE)
```

- ▶ $2190 \times 5000 X$ genotype
- ▶ $2190 \times 1 y$ response
- ▶ Dashed lines: causal variants

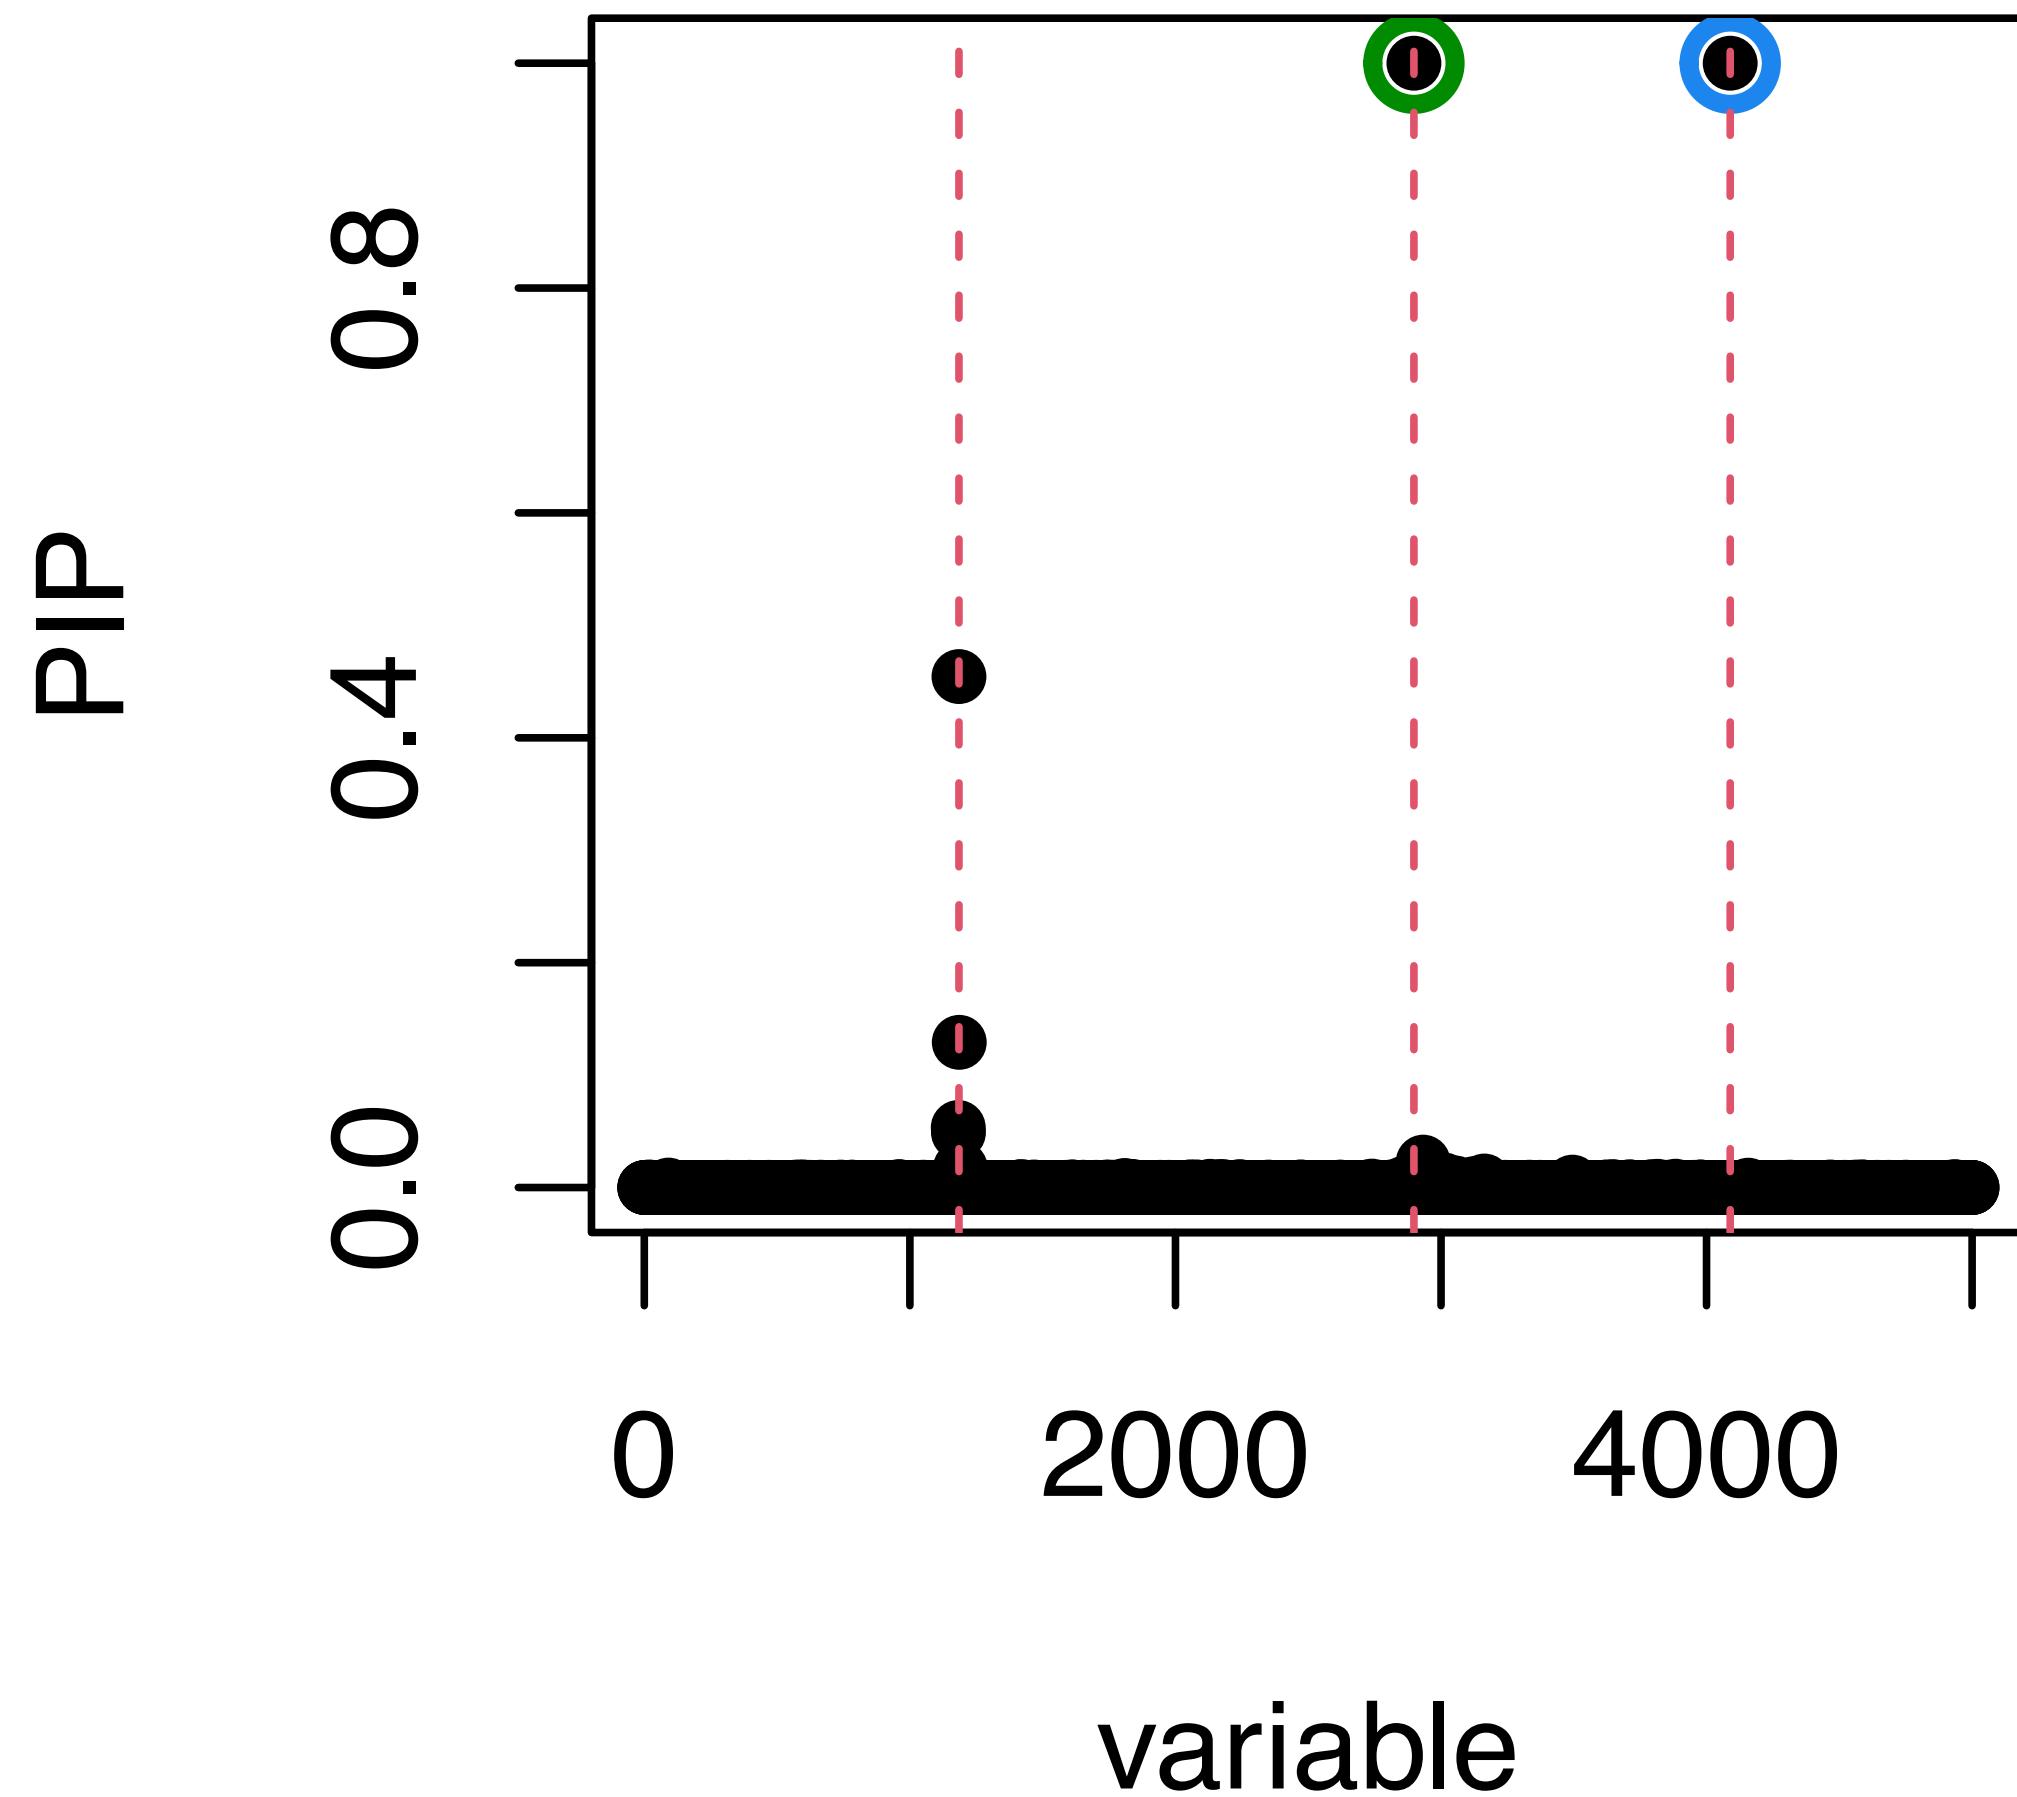

Run SuSiE to identify causal variants

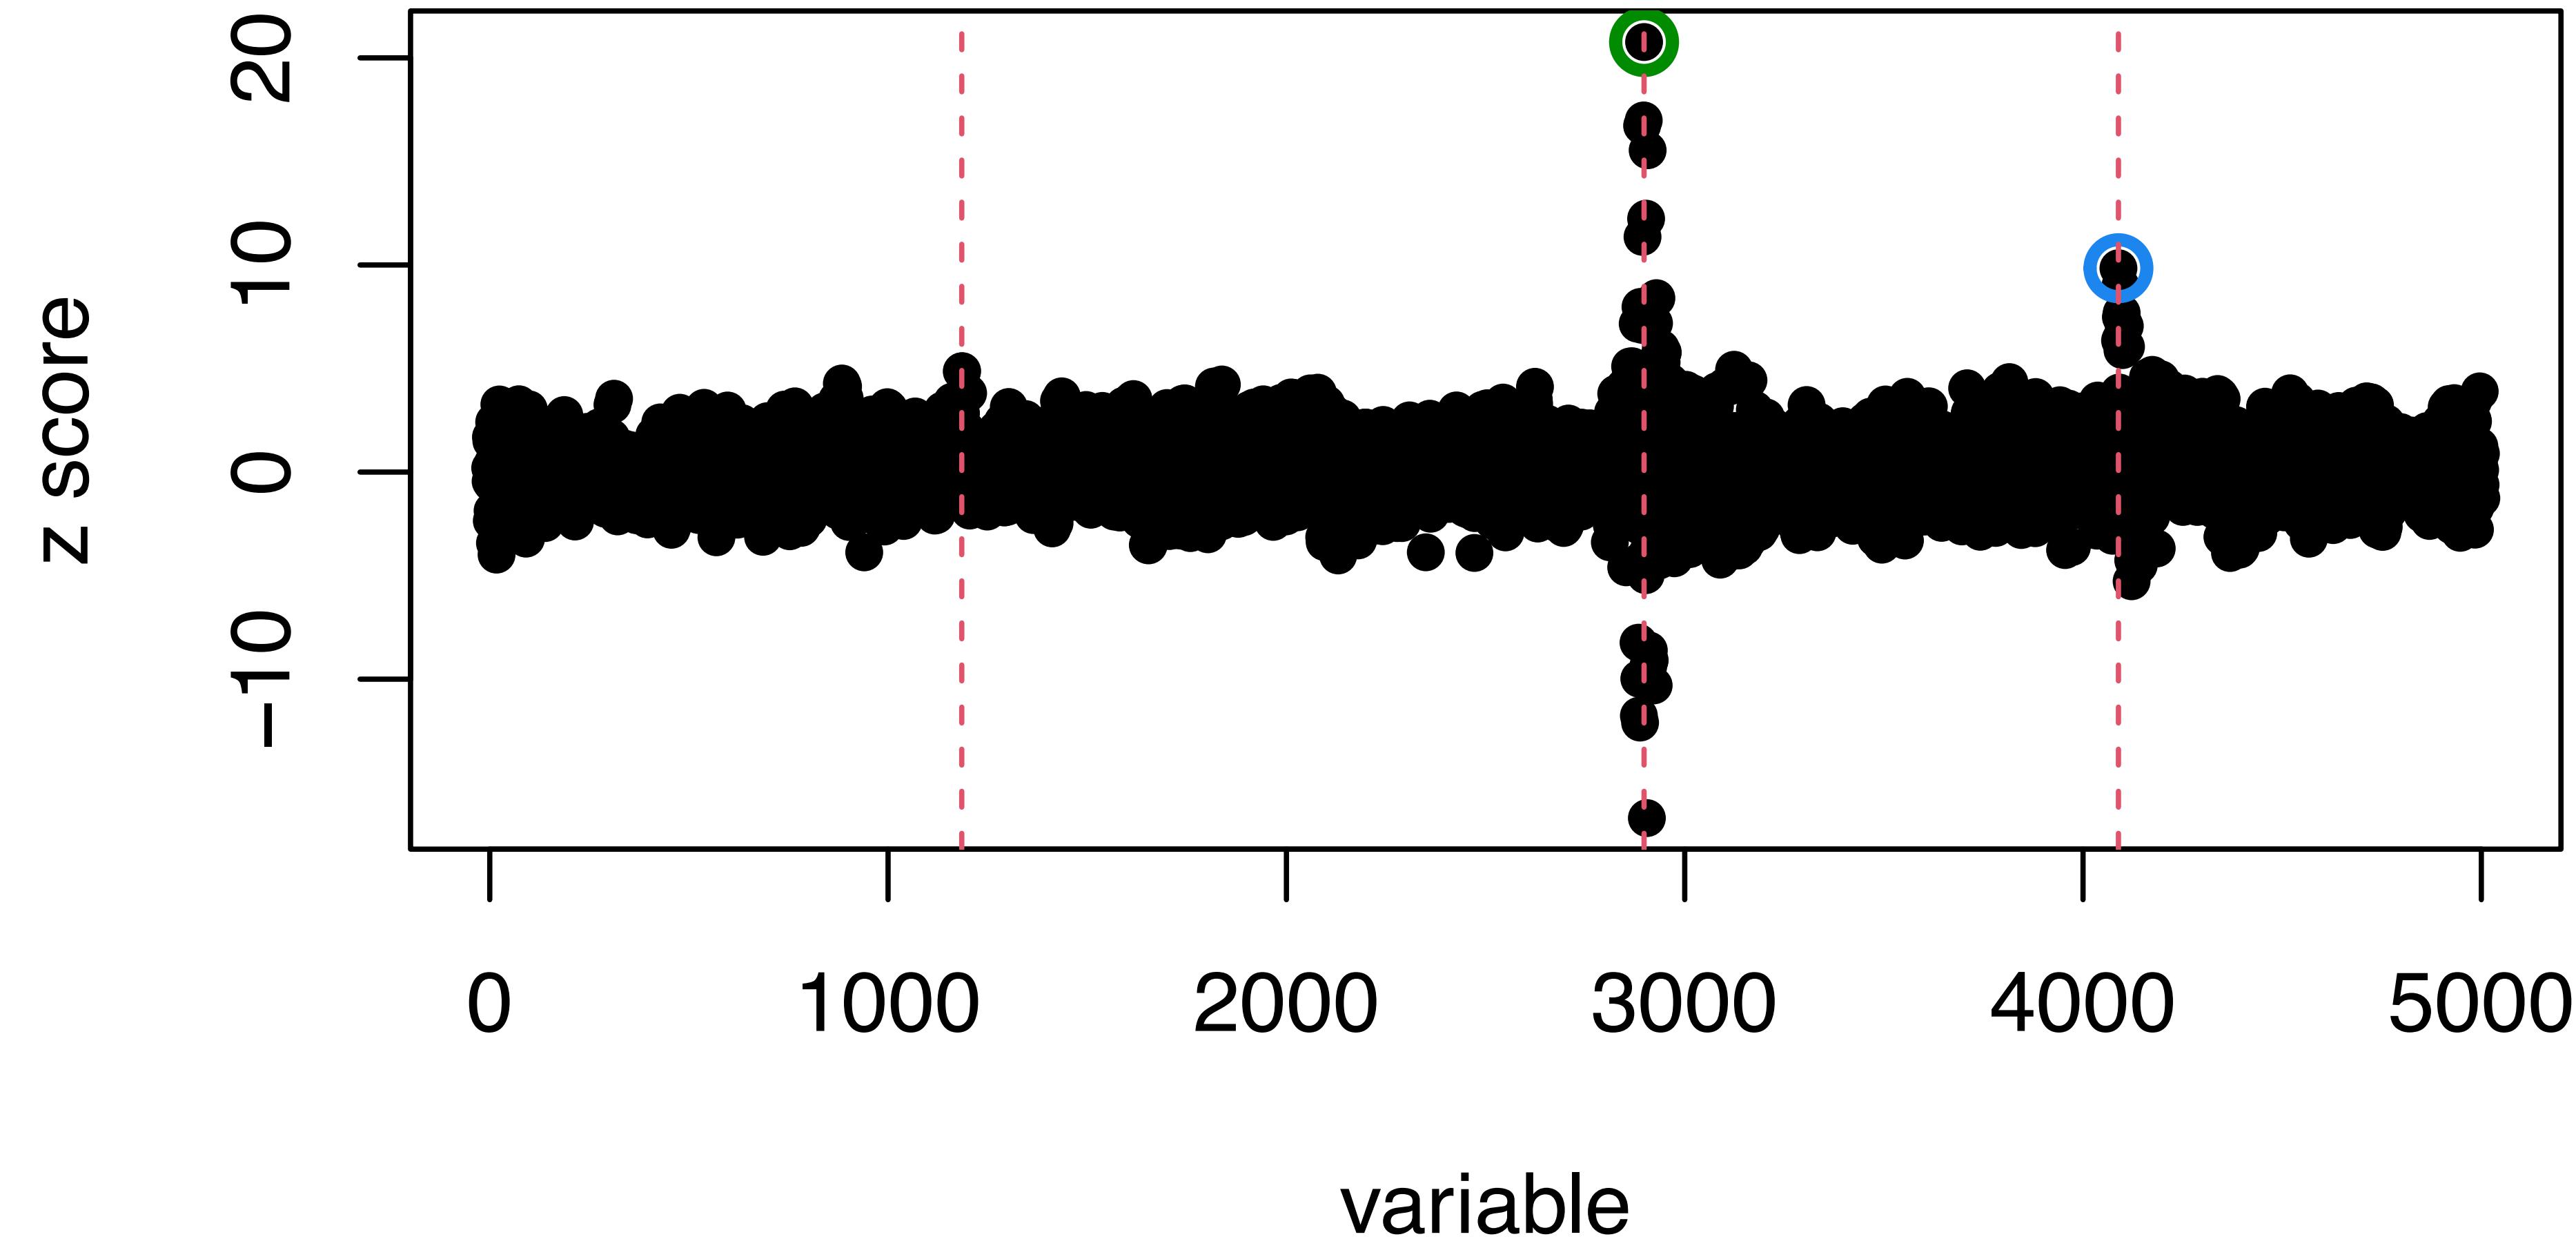

```
library(susieR)

susie.full <-
  susie(xx, y, L = 30,
compute_univariate_zscore=TRUE)
```

- ▶ $2190 \times 5000 X$ genotype
- ▶ $2190 \times 1 y$ response
- ▶ Dashed lines: causal variants

What if we only have a summary statistics vector?

z-scores...

How can we calculate summary z-scores?

```
## compute X'y  
xty <- crossprod(xx, y)  
  
## compute x'x  
x2 <- colSums(xx^2)  
  
## Maximum likelihood  
beta.hat <- xty / x2  
se.hat <- 1/sqrt(x2)  
z <- beta.hat / se.hat
```

We can estimate z-scores...

$$\hat{Z}_j = \sum_{i=1}^n X_{ij} Y_i / \sigma_\epsilon \sqrt{n}$$

for all $j \in [p]$.
assuming $\sigma_\epsilon \approx 1$.

Note: The above assumption is not bad because most genetic effects explain a relatively small portion of phenotypic variability, and phenotype vectors are standardized.

Why do we model z-scores (or other summary statistics)?

- ▶ There is no privacy concern
- ▶ Directly translate to GWAS p-values
- ▶ A majority of GWAS variants are common
- ▶ LD structures are similar within each ancestry group

Moreover, we normally don't have a full genotype matrix

```
## a random subset of individuals
## rr <- sample(nrow(xx), 300)

## genotype information of this subset
xx.sub <- xtot[rr, , drop = FALSE]

## true phenotype vector y not observed
y.true <- xtot[rr, sim$causal, drop=F] %*% sim$theta
```

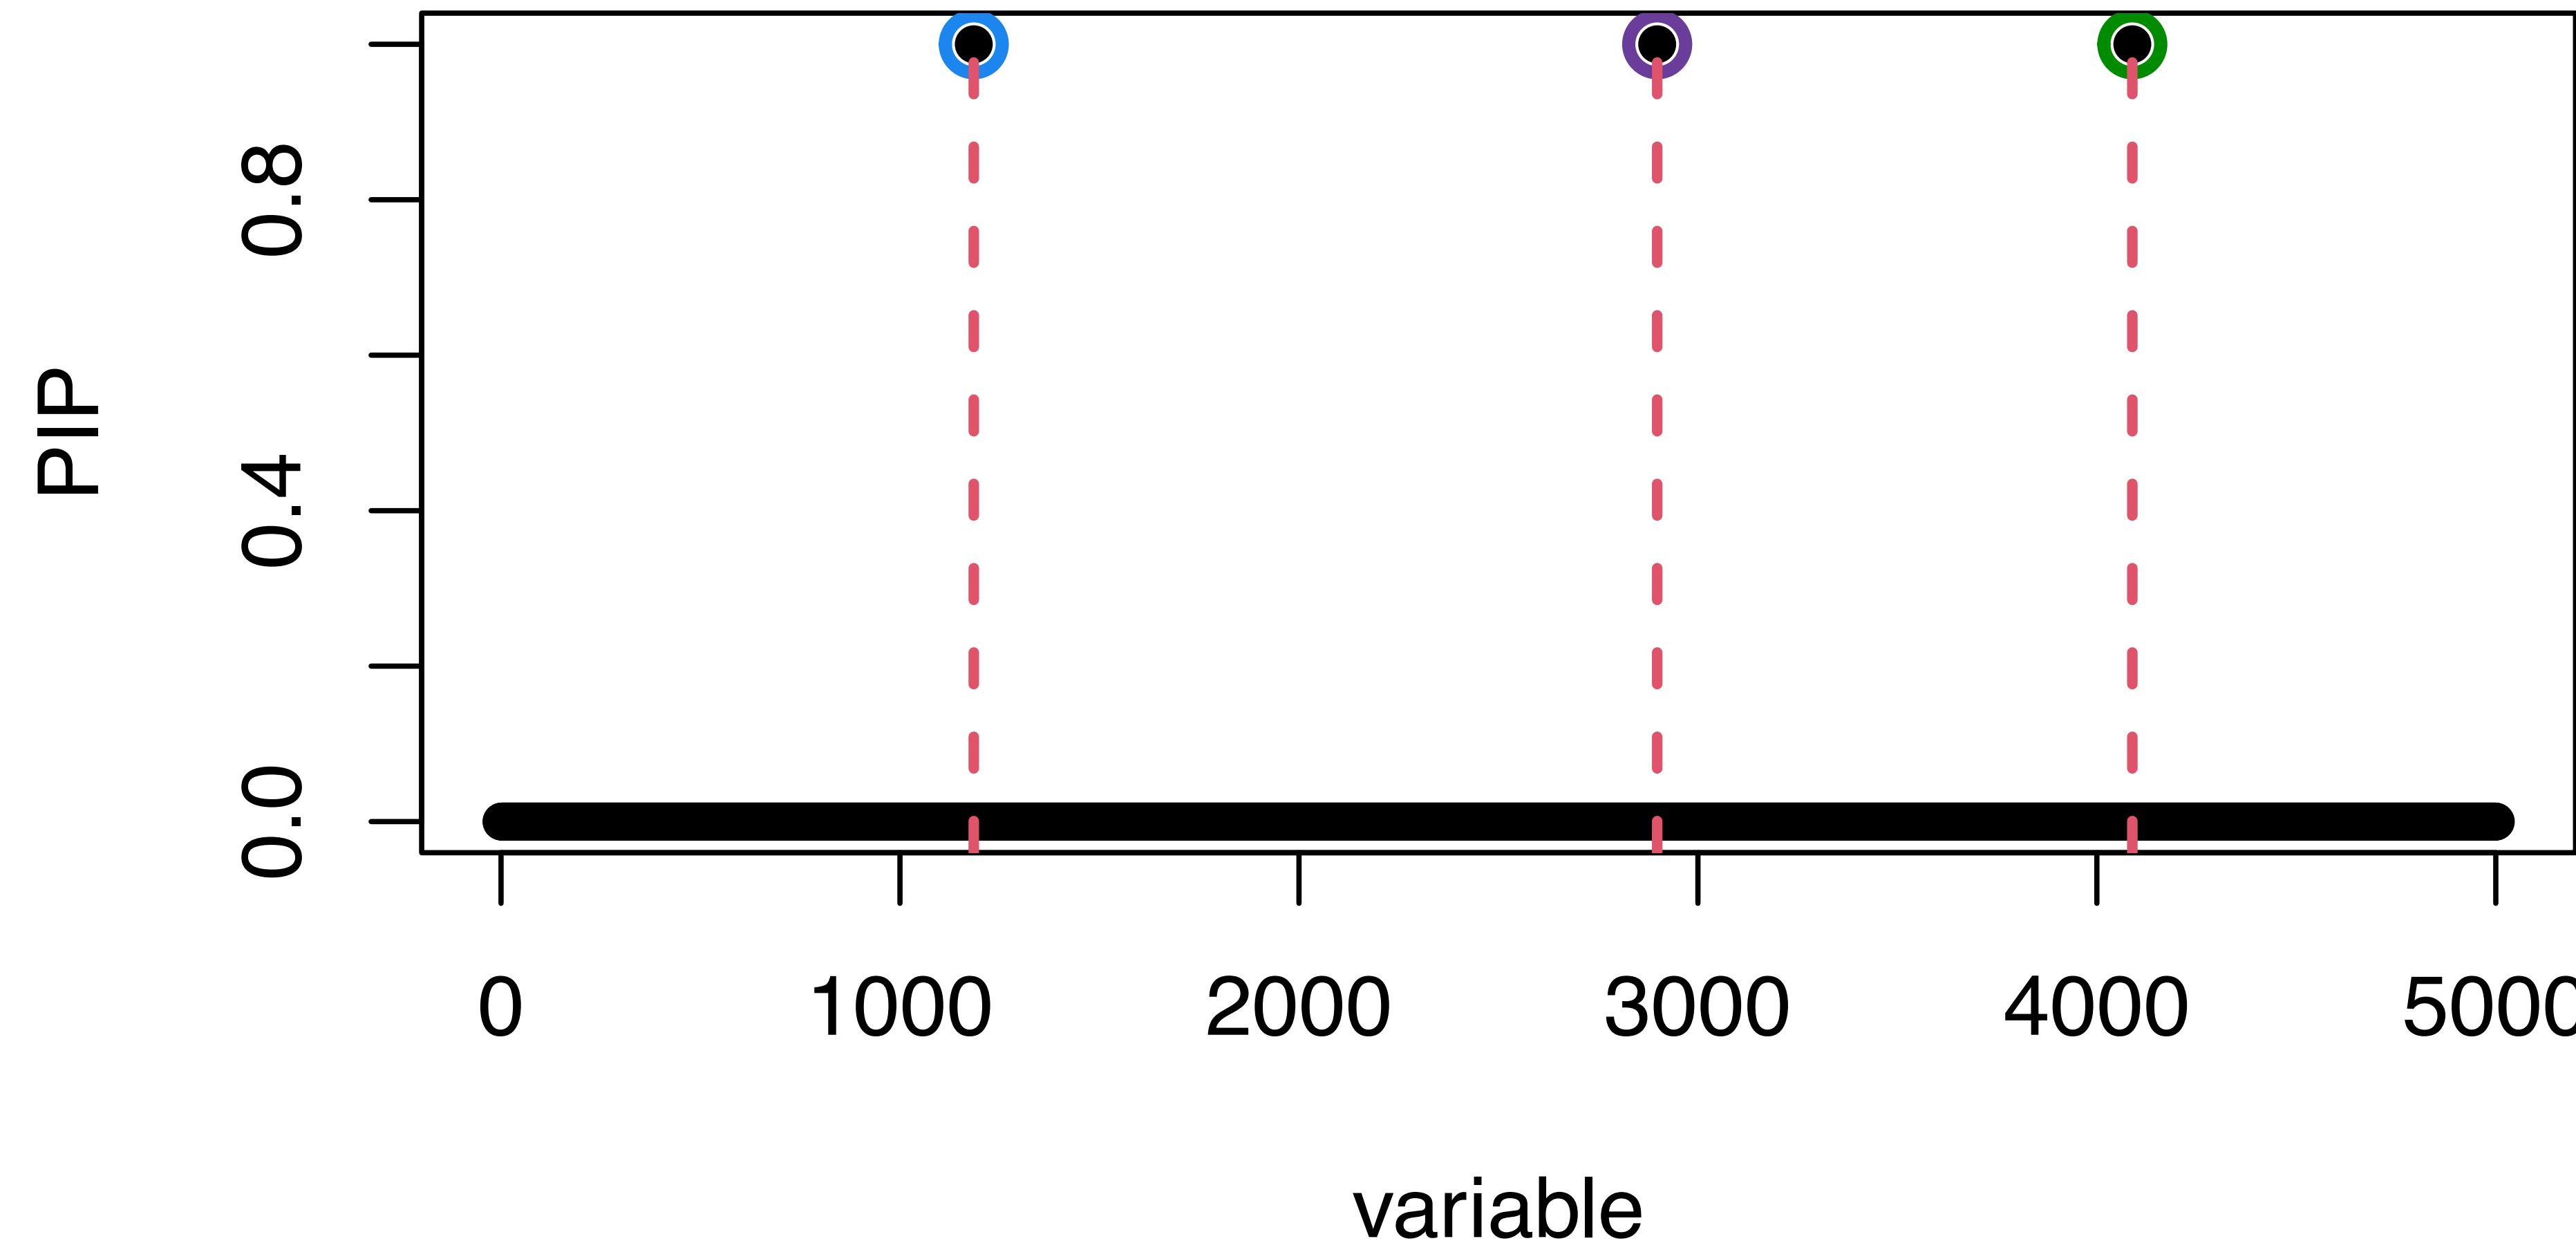

Let's say that we only have 300 individuals available independent of the full 2190 GWAS samples.

What do we have to carry out summary-based inference?

- ▶ \mathbf{z} : $p \times 1$ z-score vector
- ▶ $\hat{\mathbf{X}}$: $m \times p$ genotype matrix $m \ll n$
- ▶ Typically we have $\hat{\mathcal{R}}$: $X^\top X/m$ LD matrix
- ▶ If $\hat{\mathbf{X}}$ is a submatrix of X , in-sample $\hat{\mathcal{R}}$ LD
- ▶ Otherwise, we can use an LD matrix computed in some reference cohorts (e.g., 1000G, UK Biobank)

What if we had “true” phenotype values?

We could have run `susie.out <- susie(xx.sub, y.true)`

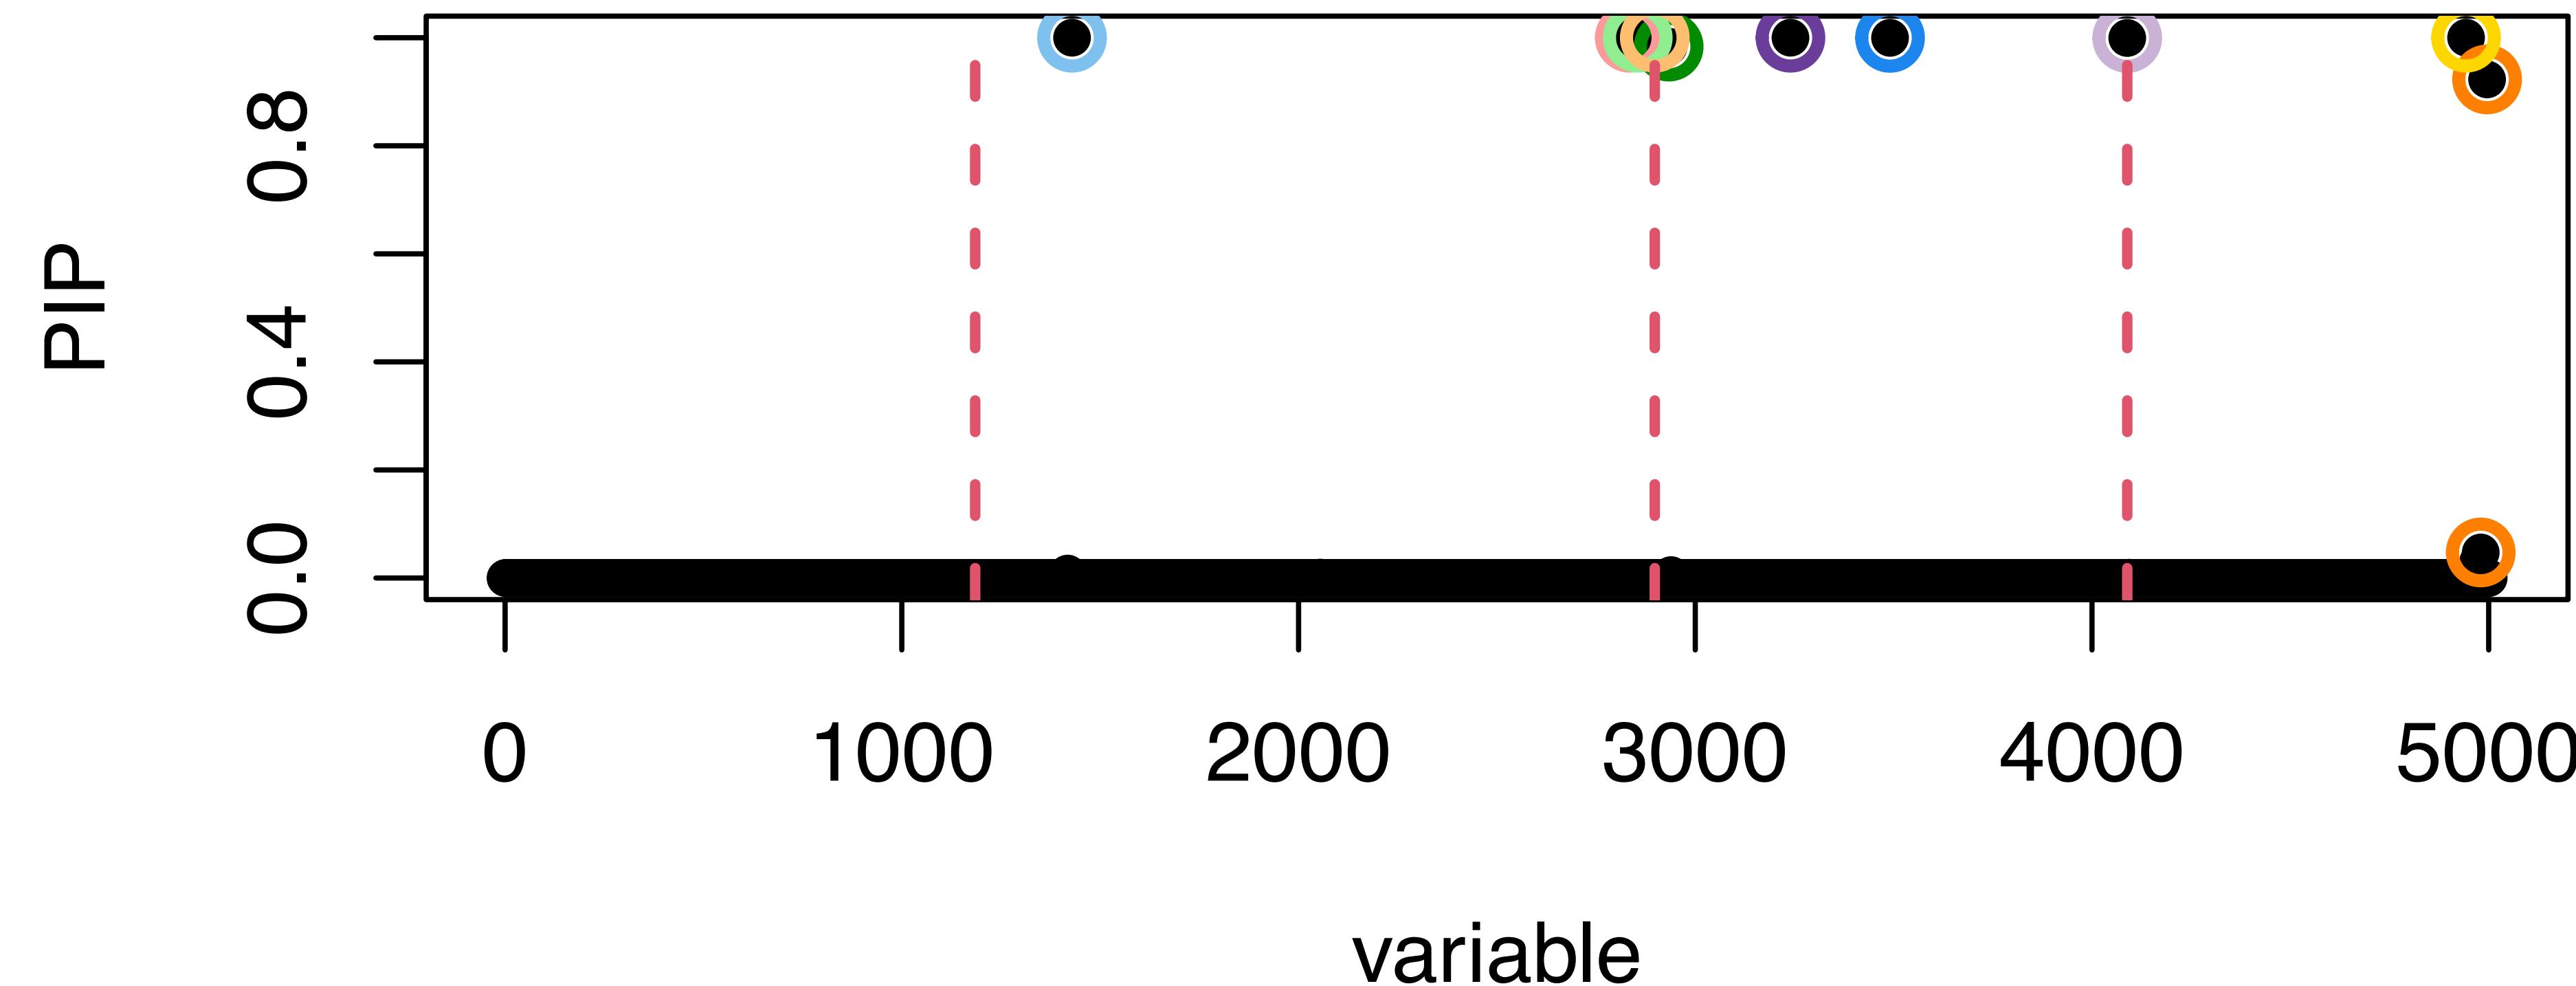

SuSiE-RSS (regression with summary statistics)

$$\mathbf{z} = \mathbf{R} \frac{\sqrt{n}}{\sigma} \boldsymbol{\theta} + \tilde{\boldsymbol{\epsilon}}, \quad \tilde{\boldsymbol{\epsilon}} \sim \mathcal{N}(\mathbf{0}, \mathbf{R})$$

Zou, Carbonetto, Wang, Stephens, *PLoS Genetics* (2022)

SuSiE-RSS may produce so many false positives...

```
susie.rss <- susie_rss(z, R=cov(xx.sub), n=nrow(xx))
```

Can we simply predict unobserved \mathbf{Y} ?

```
library(rsvd) # faster than svd  
  
## [U, D, V'] = svd(X/sqrt(n))  
nn <- nrow(xx.sub)  
.svd <- rsvd(xx.sub / sqrt(nn))  
  
## U * inv(D) * V'  
U <- .svd$u  
Vt <- t(.svd$v)  
D <- .svd$d + .01  
proj <-  
  sweep(U, 2, D, `/) %*% Vt  
y.hat <- proj %*% z
```

Polygenic risk prediction:

1. Roughly estimate parameter θ

$$\mathbf{z} \sim \mathcal{N}(\hat{\mathbf{R}}\theta, \hat{\mathbf{R}})$$

$$\theta \sim \mathcal{N}(\hat{\mathbf{R}}^{-1}\mathbf{z}, \hat{\mathbf{R}}^{-1})$$

2. We can then predict/project the effects

$$\mathbf{y} \leftarrow \hat{\mathbf{X}}\hat{\theta}$$

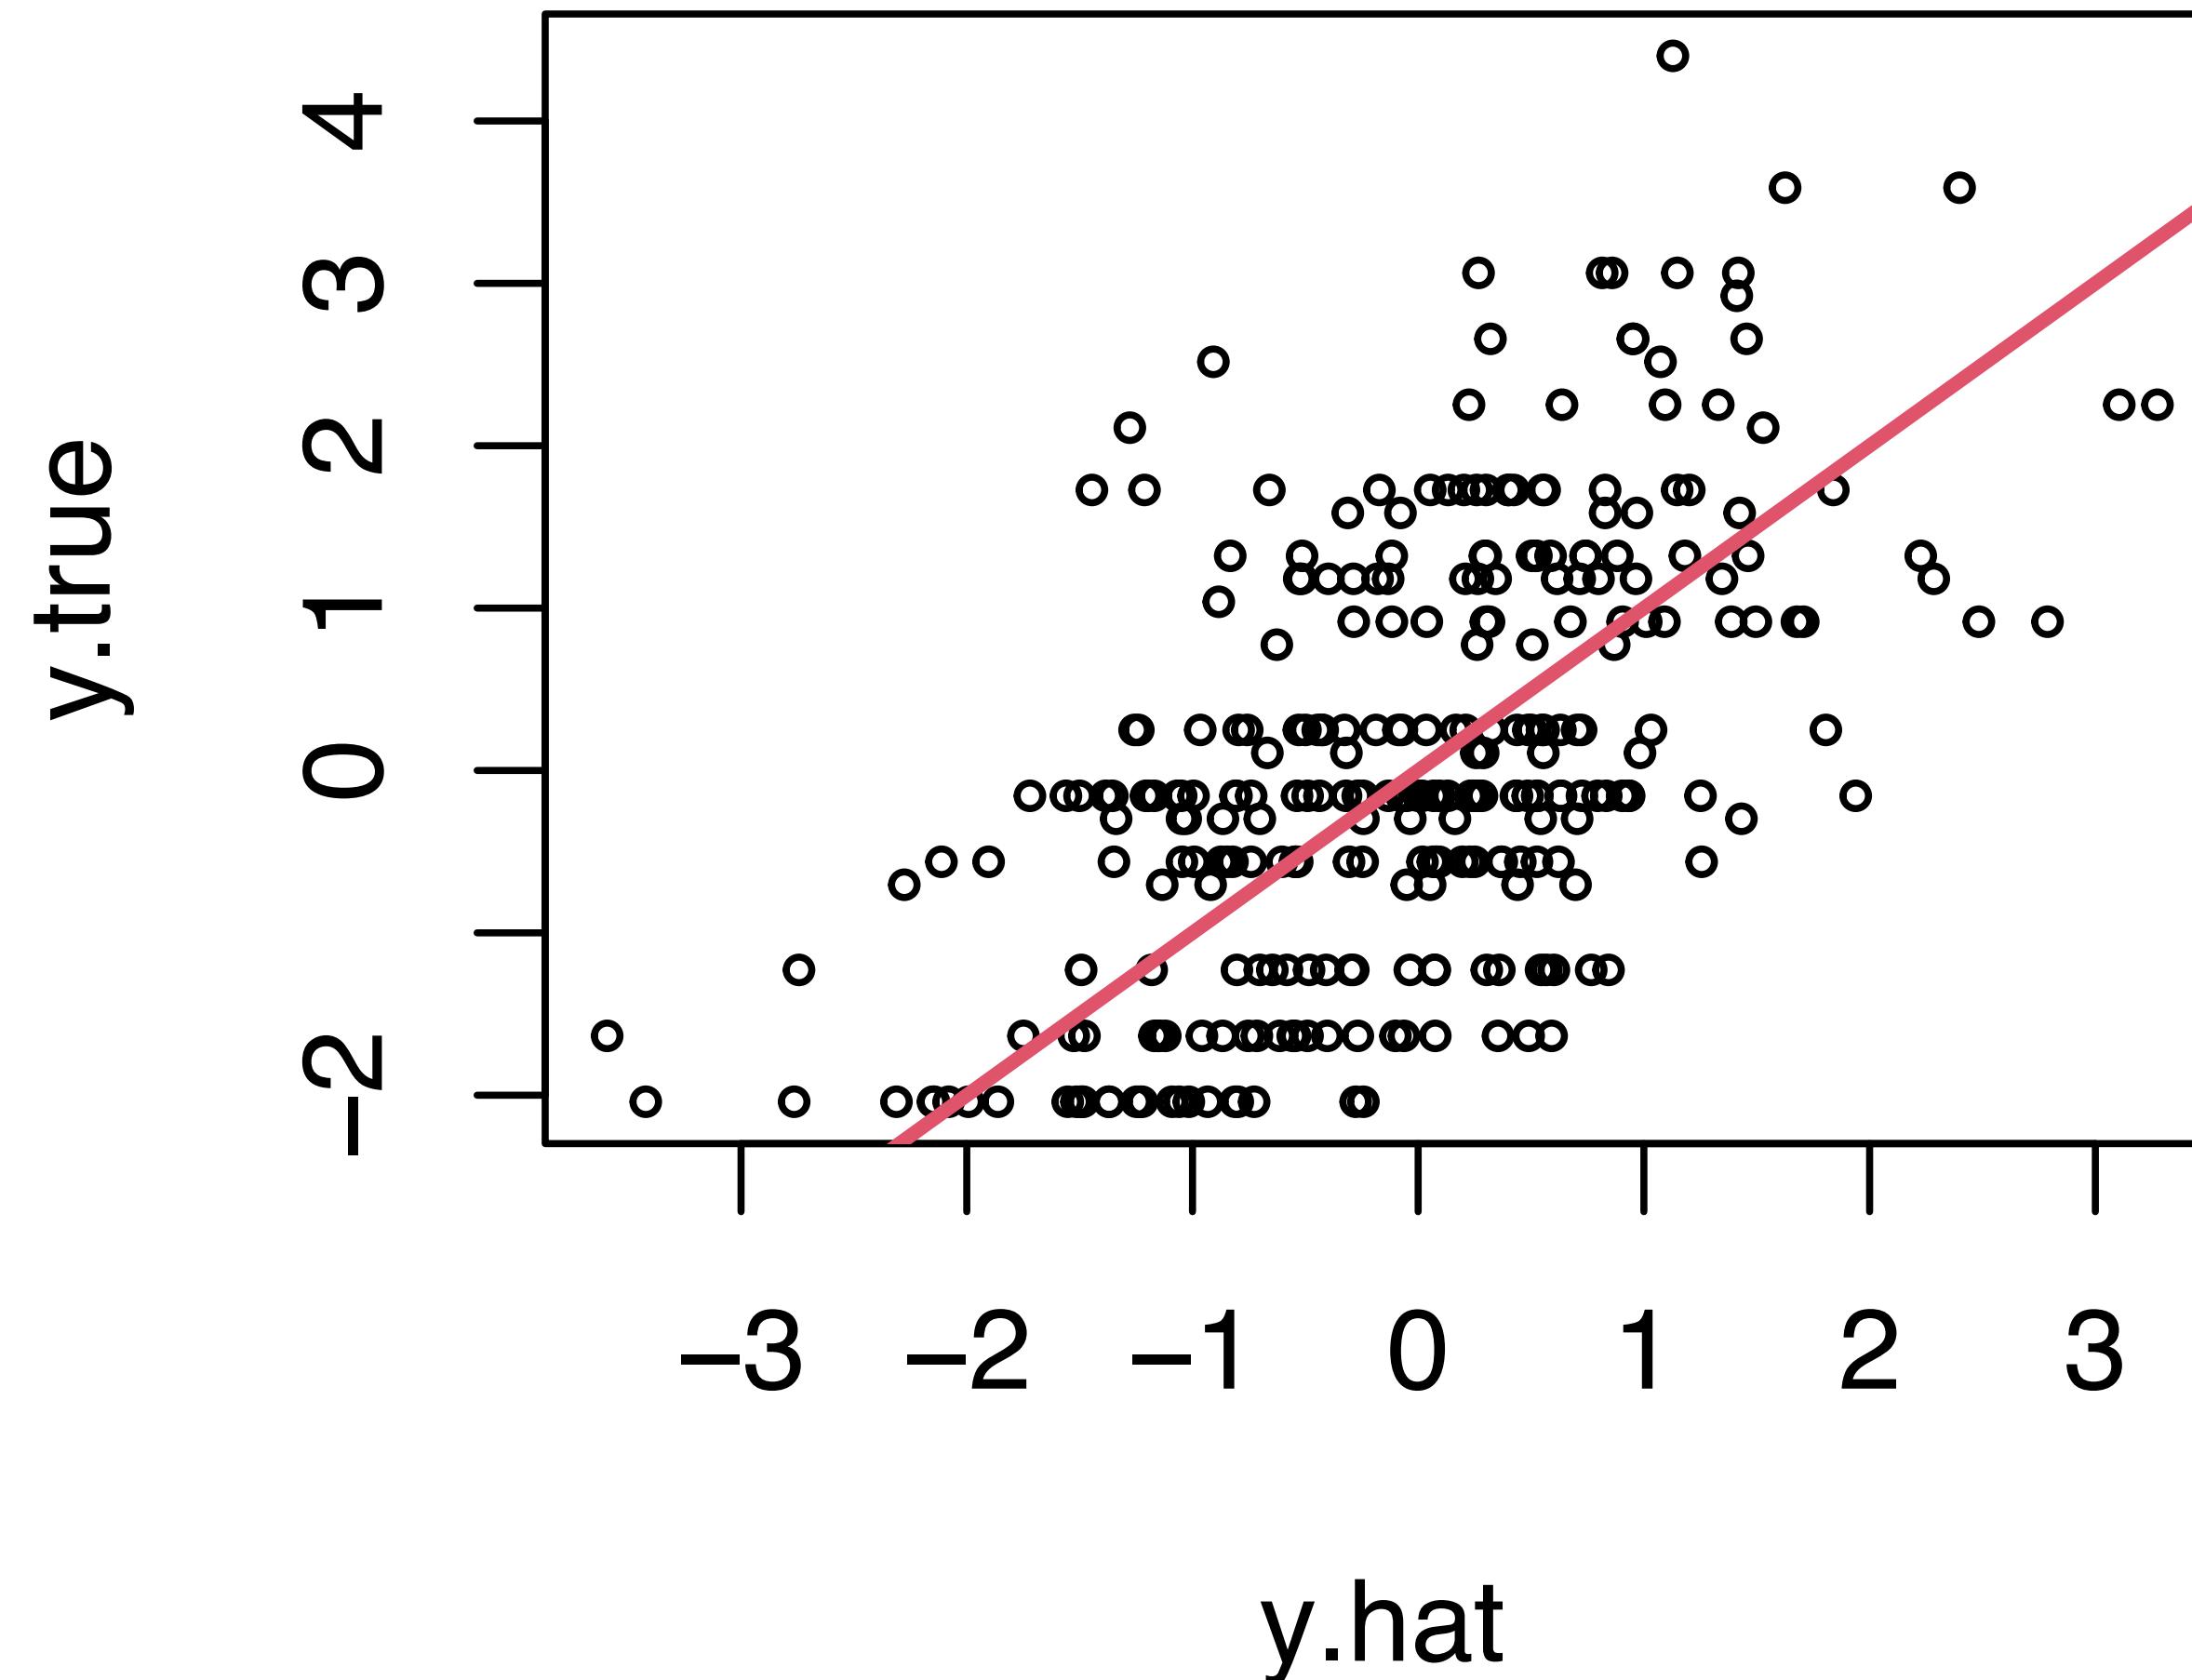

Here, we used the pseudo-inverse of the sample covariance matrix $\hat{\mathbf{R}}^{-1} = \mathbf{V}\mathbf{D}^{-2}\mathbf{V}^\top$ followed by SVD, $[U, D, V^\top] = \text{svd}(n^{-1/2}X)$. For matrix algebra, refer to Matrix Cookbook.

Can we simply predict unobserved Y?

```
library(rsvd) # faster than svd

## [U, D, V'] = svd(X/sqrt(n))
nn <- nrow(xx.sub)
.svd <- rsvd(xx.sub / sqrt(nn))

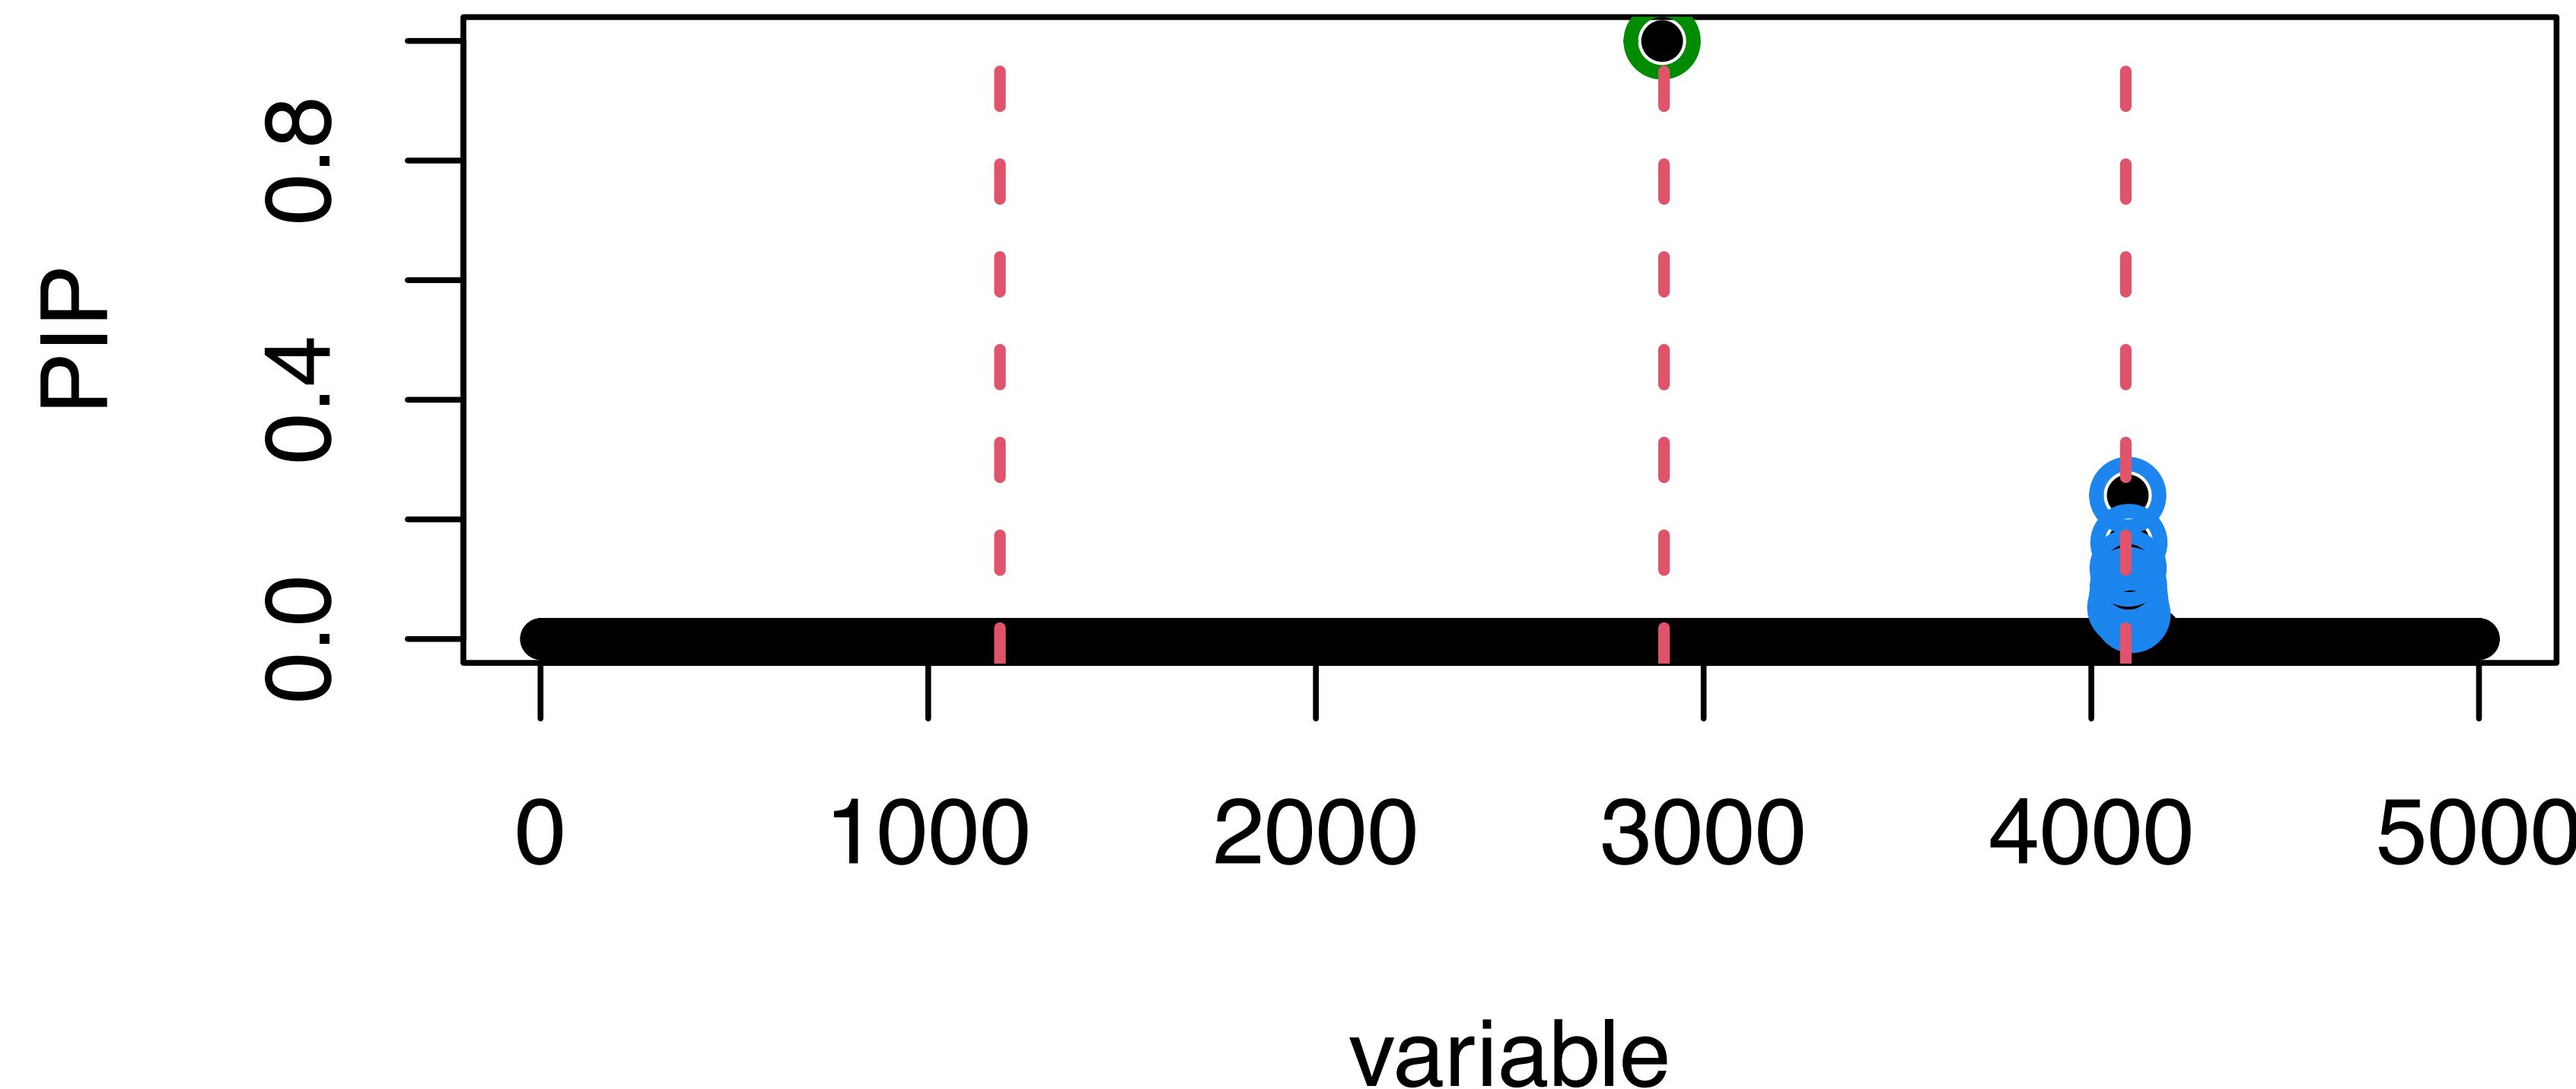

## U * inv(D) * V'
U <- .svd$u
Vt <- t(.svd$v)
D <- .svd$d + .01
proj <-
  sweep(U, 2, D, `/) %*% Vt
y.hat <- proj %*% z
```

Here, we used the pseudo-inverse of the sample covariance matrix $\hat{R}^{-1} = VD^{-2}V^\top$ followed by SVD, $[U, D, V^\top] = \text{svd}(n^{-1/2}X)$. For matrix algebra, refer to Matrix Cookbook.

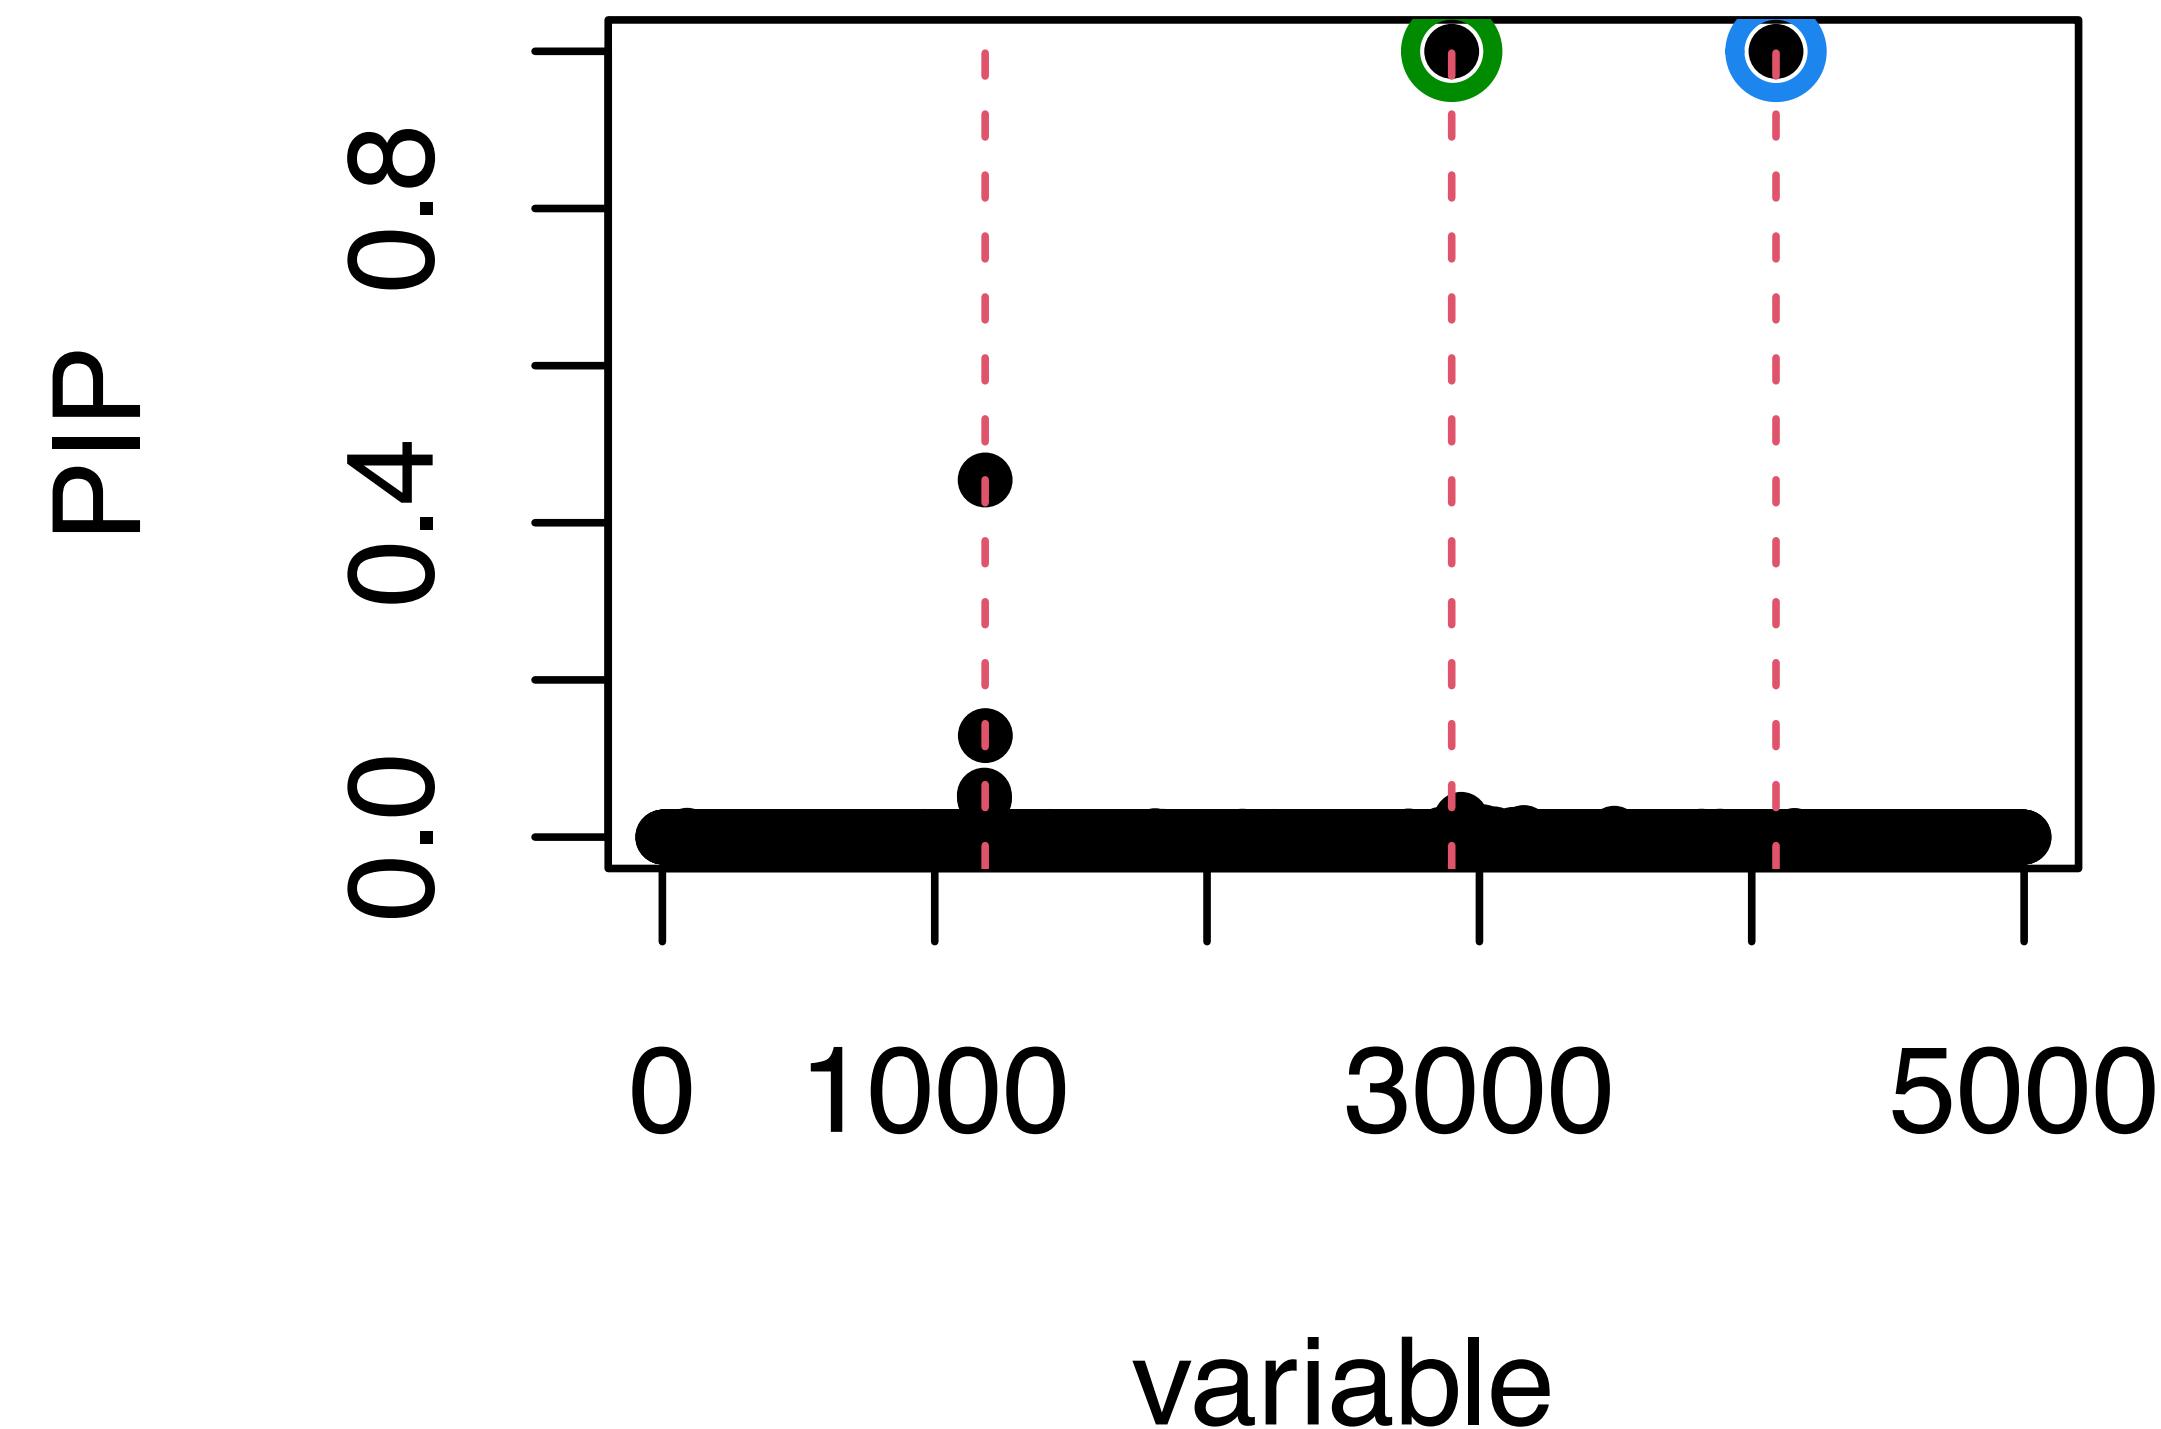

We can run the same susie method as if we observed phenotypes

```
susie.prs <- susie(xx.sub, y.hat)
```

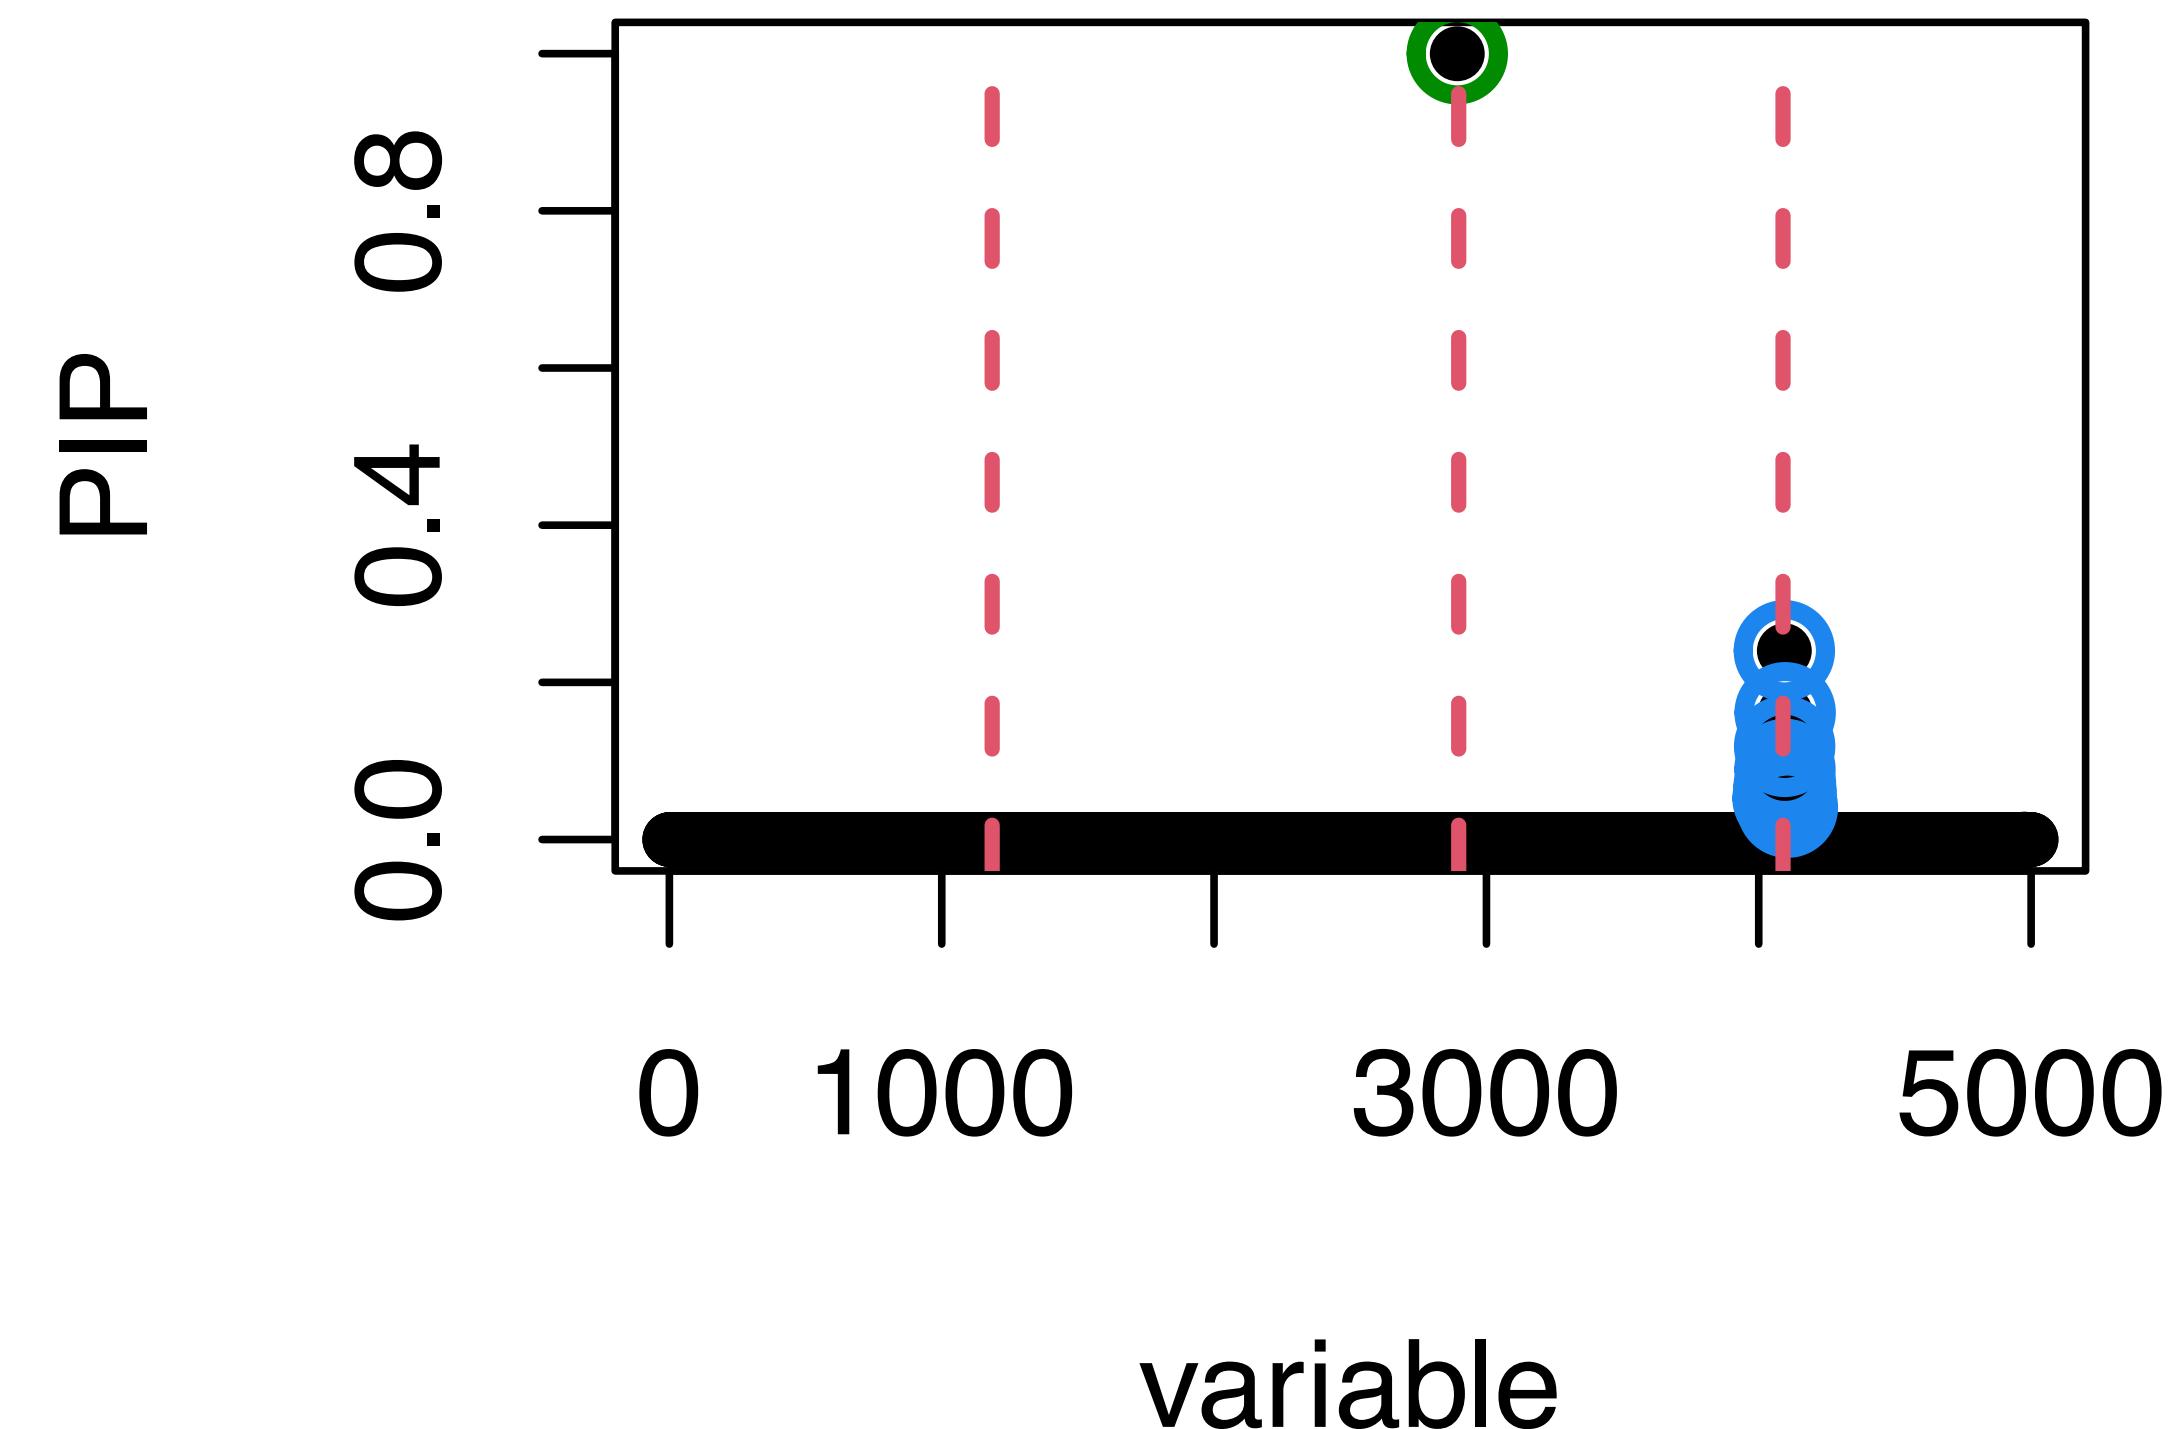

Much fewer false discoveries and competitive power

LD score (LDSC) regression to model χ^2 statistics

What is a generative model for a χ_j^2 ($= Z_j^2$) statistics vector?

We have seen this relationship in the fine-mapping model:

$$Z_j \underset{\text{univariate, summary stat}}{=} \frac{\sqrt{n}}{\sigma} \sum_k R_{jk} \underset{\text{LD between j and k}}{\theta_k} + \epsilon_j \underset{\text{multivariate, true effect}}{}$$

where $\epsilon \sim \mathcal{N}(0, 1)$.

LD score (LDSC) regression to model χ^2 statistics

What is a generative model for a χ_j^2 ($= Z_j^2$) statistics vector?

Simply plugging Z_j in the equation,

$$\mathbb{E}[\chi_j^2] = \mathbb{E}[Z_j^2] = \mathbb{E}\left(\sqrt{n} \sum_k R_{jk} \theta_k + \epsilon_j\right)^2$$

Bulik-Sullivan *et al.*, *Nature Genetics* (2014); Finucane *et al.*, *Nature Genetics* (2015)

LD score (LDSC) regression to model χ^2 statistics

What is a generative model for a χ_j^2 ($= Z_j^2$) statistics vector?

Simply plugging Z_j in the equation,

$$\mathbb{E}[\chi_j^2] = \mathbb{E}[Z_j^2] = \mathbb{E}\left(\sqrt{n} \sum_k R_{jk} \theta_k + \epsilon_j\right)^2$$

If "true" multivariate effect for each variant is independent of other variants' effects, i.e., $\mathbb{E}[\theta_k \theta_j] = 0$ for all $k \neq j$,

$$\mathbb{E}[\chi_j^2] = n \underbrace{\sum_k R_{jk}^2 \mathbb{E}[\theta_k^2]}_{\text{LD-score}} + 1$$

Baseline LD-score regression to measure polygenic heritability

- (1) Assuming that all the variants equally contribute,

$$\mathbb{E}[\theta_k^2] = \tau/p,$$

where p is the total number of SNPs,

Baseline LD-score regression to measure polygenic heritability

(1) Assuming that all the variants
equally contribute,

$$\mathbb{E}[\theta_k^2] = \tau/p,$$

(2) defining an LD score for a
variant/SNP j as

$$l_j \stackrel{\text{def}}{=} \sum_k R_{jk}^2,$$

Baseline LD-score regression to measure polygenic heritability

(1) Assuming that all the variants equally contribute,

$$\mathbb{E}[\theta_k^2] = \tau/p,$$

(2) defining an LD score for a variant/SNP j as

$$l_j \stackrel{\text{def}}{=} \sum_k R_{jk}^2,$$

We get

$$\mathbb{E}[\chi_j^2] = n \underbrace{\sum_k R_{jk}^2}_{\text{LD-score}} \mathbb{E}[\theta_k^2] + 1$$

Baseline LD-score regression to measure polygenic heritability

(1) Assuming that all the variants equally contribute,

$$\mathbb{E}[\theta_k^2] = \tau/p,$$

(2) defining an LD score for a variant/ SNP j as

$$l_j \stackrel{\text{def}}{=} \sum_k R_{jk}^2,$$

We get

$$\mathbb{E}[\chi_j^2] = n \underbrace{\sum_k R_{jk}^2}_{\text{LD-score}} \mathbb{E}[\theta_k^2] + 1 = \frac{n}{\text{sample size}} l_j \frac{\tau}{p} + 1$$

LD score per SNP heritability

where p is the total number of SNPs.

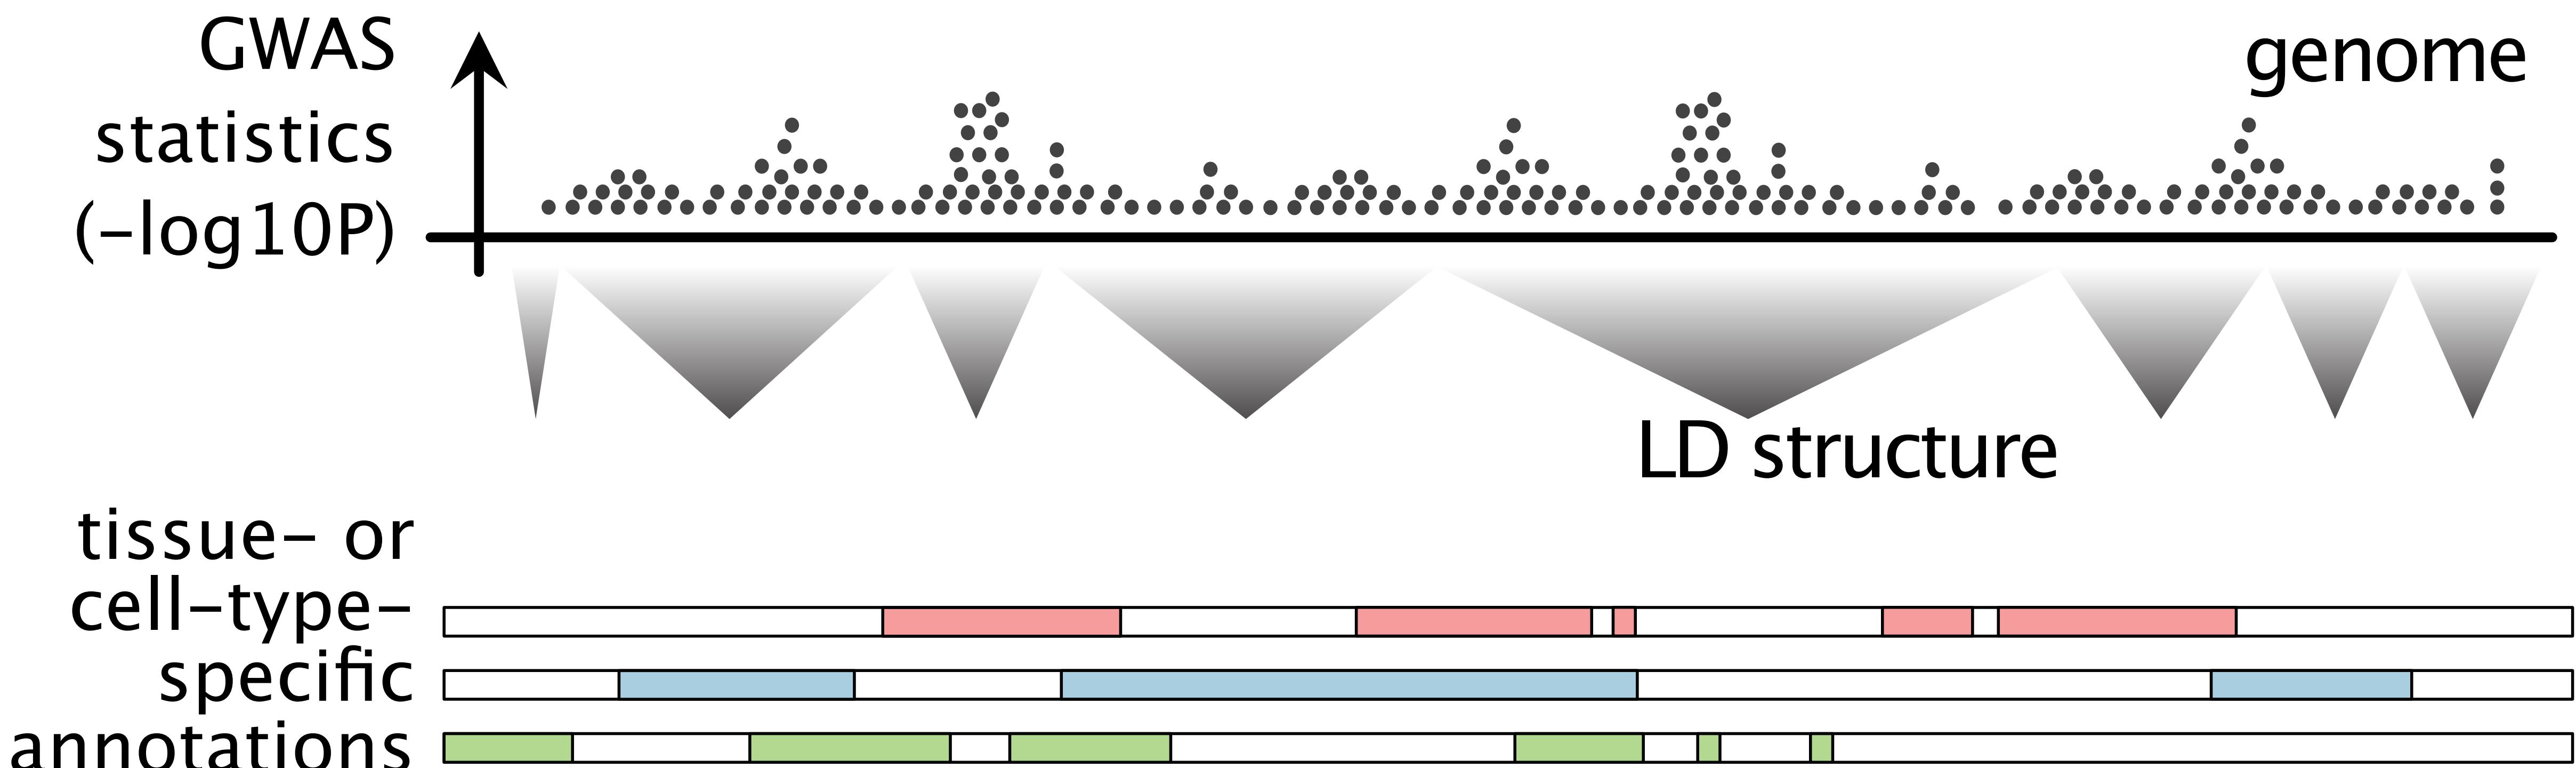

Baseline LD-score regression to measure polygenic heritability

We can treat the relationships as a regression model and find the heritability parameters by regressing the observed χ^2 statistics on the reference LD scores l_j :

$$\begin{pmatrix} \chi_1^2 \\ \vdots \\ \chi_j^2 \\ \vdots \end{pmatrix} \sim \frac{n}{p} \begin{pmatrix} l_1 \\ \vdots \\ l_j \\ \vdots \end{pmatrix} \text{ per SNP heritability } \tau + n\phi \text{ genomic inflation} + 1 \text{ null}$$

If the intercept of $\{\chi_j^2\}$ deviate from 1, we can interpret that the GWAS statistics are inflated by some unadjusted population structures or other confounding factors.

Stratified LD-score regression partitions total heritability into multiple genomic annotations

Stratified LD-score regression in math

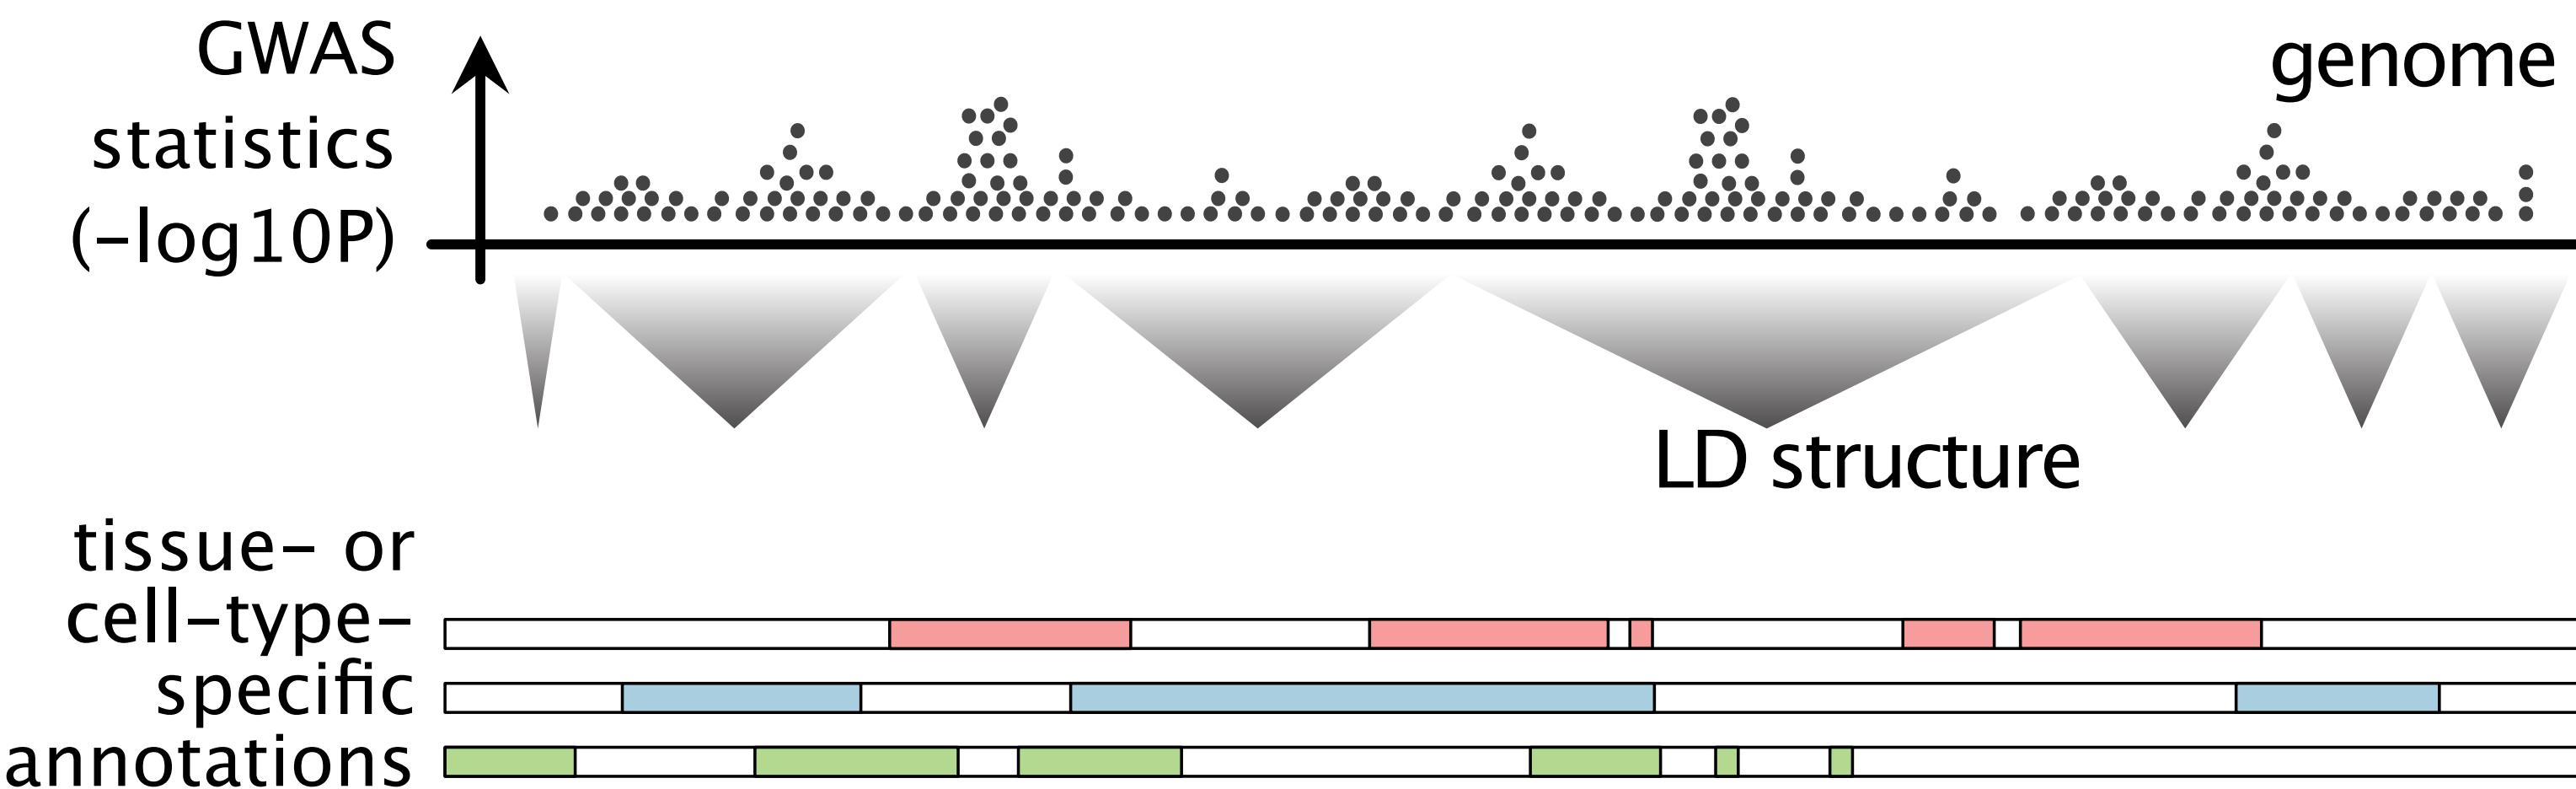

When genome is partitioned by annotations (e.g., epigenetic tracks)

$$\mathbb{E}[\chi_j^2] = \frac{n}{p} \sum_t l_{jt} \tau_t + n\phi + 1$$

stratified heritability genomic inflation null

where we use partitioned LD-scores for each annotation type t

$$l_{jt} = \sum_k R_{jk}^2 I\{k \in \mathcal{A}_t\}.$$

Stratified LD-score regression in math

When genome is partitioned by annotations (e.g., epigenetic tracks)

$$\mathbb{E}[\chi_j^2] = \frac{n}{p} \sum_t l_{jt} \tau_t + n\phi + 1$$

stratified heritability genomic inflation null

where we use partitioned LD-scores for each annotation type t

$$l_{jt} = \sum_k R_{jk}^2 I\{k \in \mathcal{A}_t\}.$$

Instead of assuming a single parameter for the overall per-SNP heritability τ , we can “partition” this total heritability into annotation-type-specific ones, $\{\tau_t\}$.

Stratified LD-score regression in math

When genome is partitioned by annotations (e.g., epigenetic tracks)

$$\mathbb{E}[\chi_j^2] = \frac{n}{p} \sum_t l_{jt} \tau_t + n\phi + 1$$

stratified heritability genomic inflation null

where we use partitioned LD-scores for each annotation type t

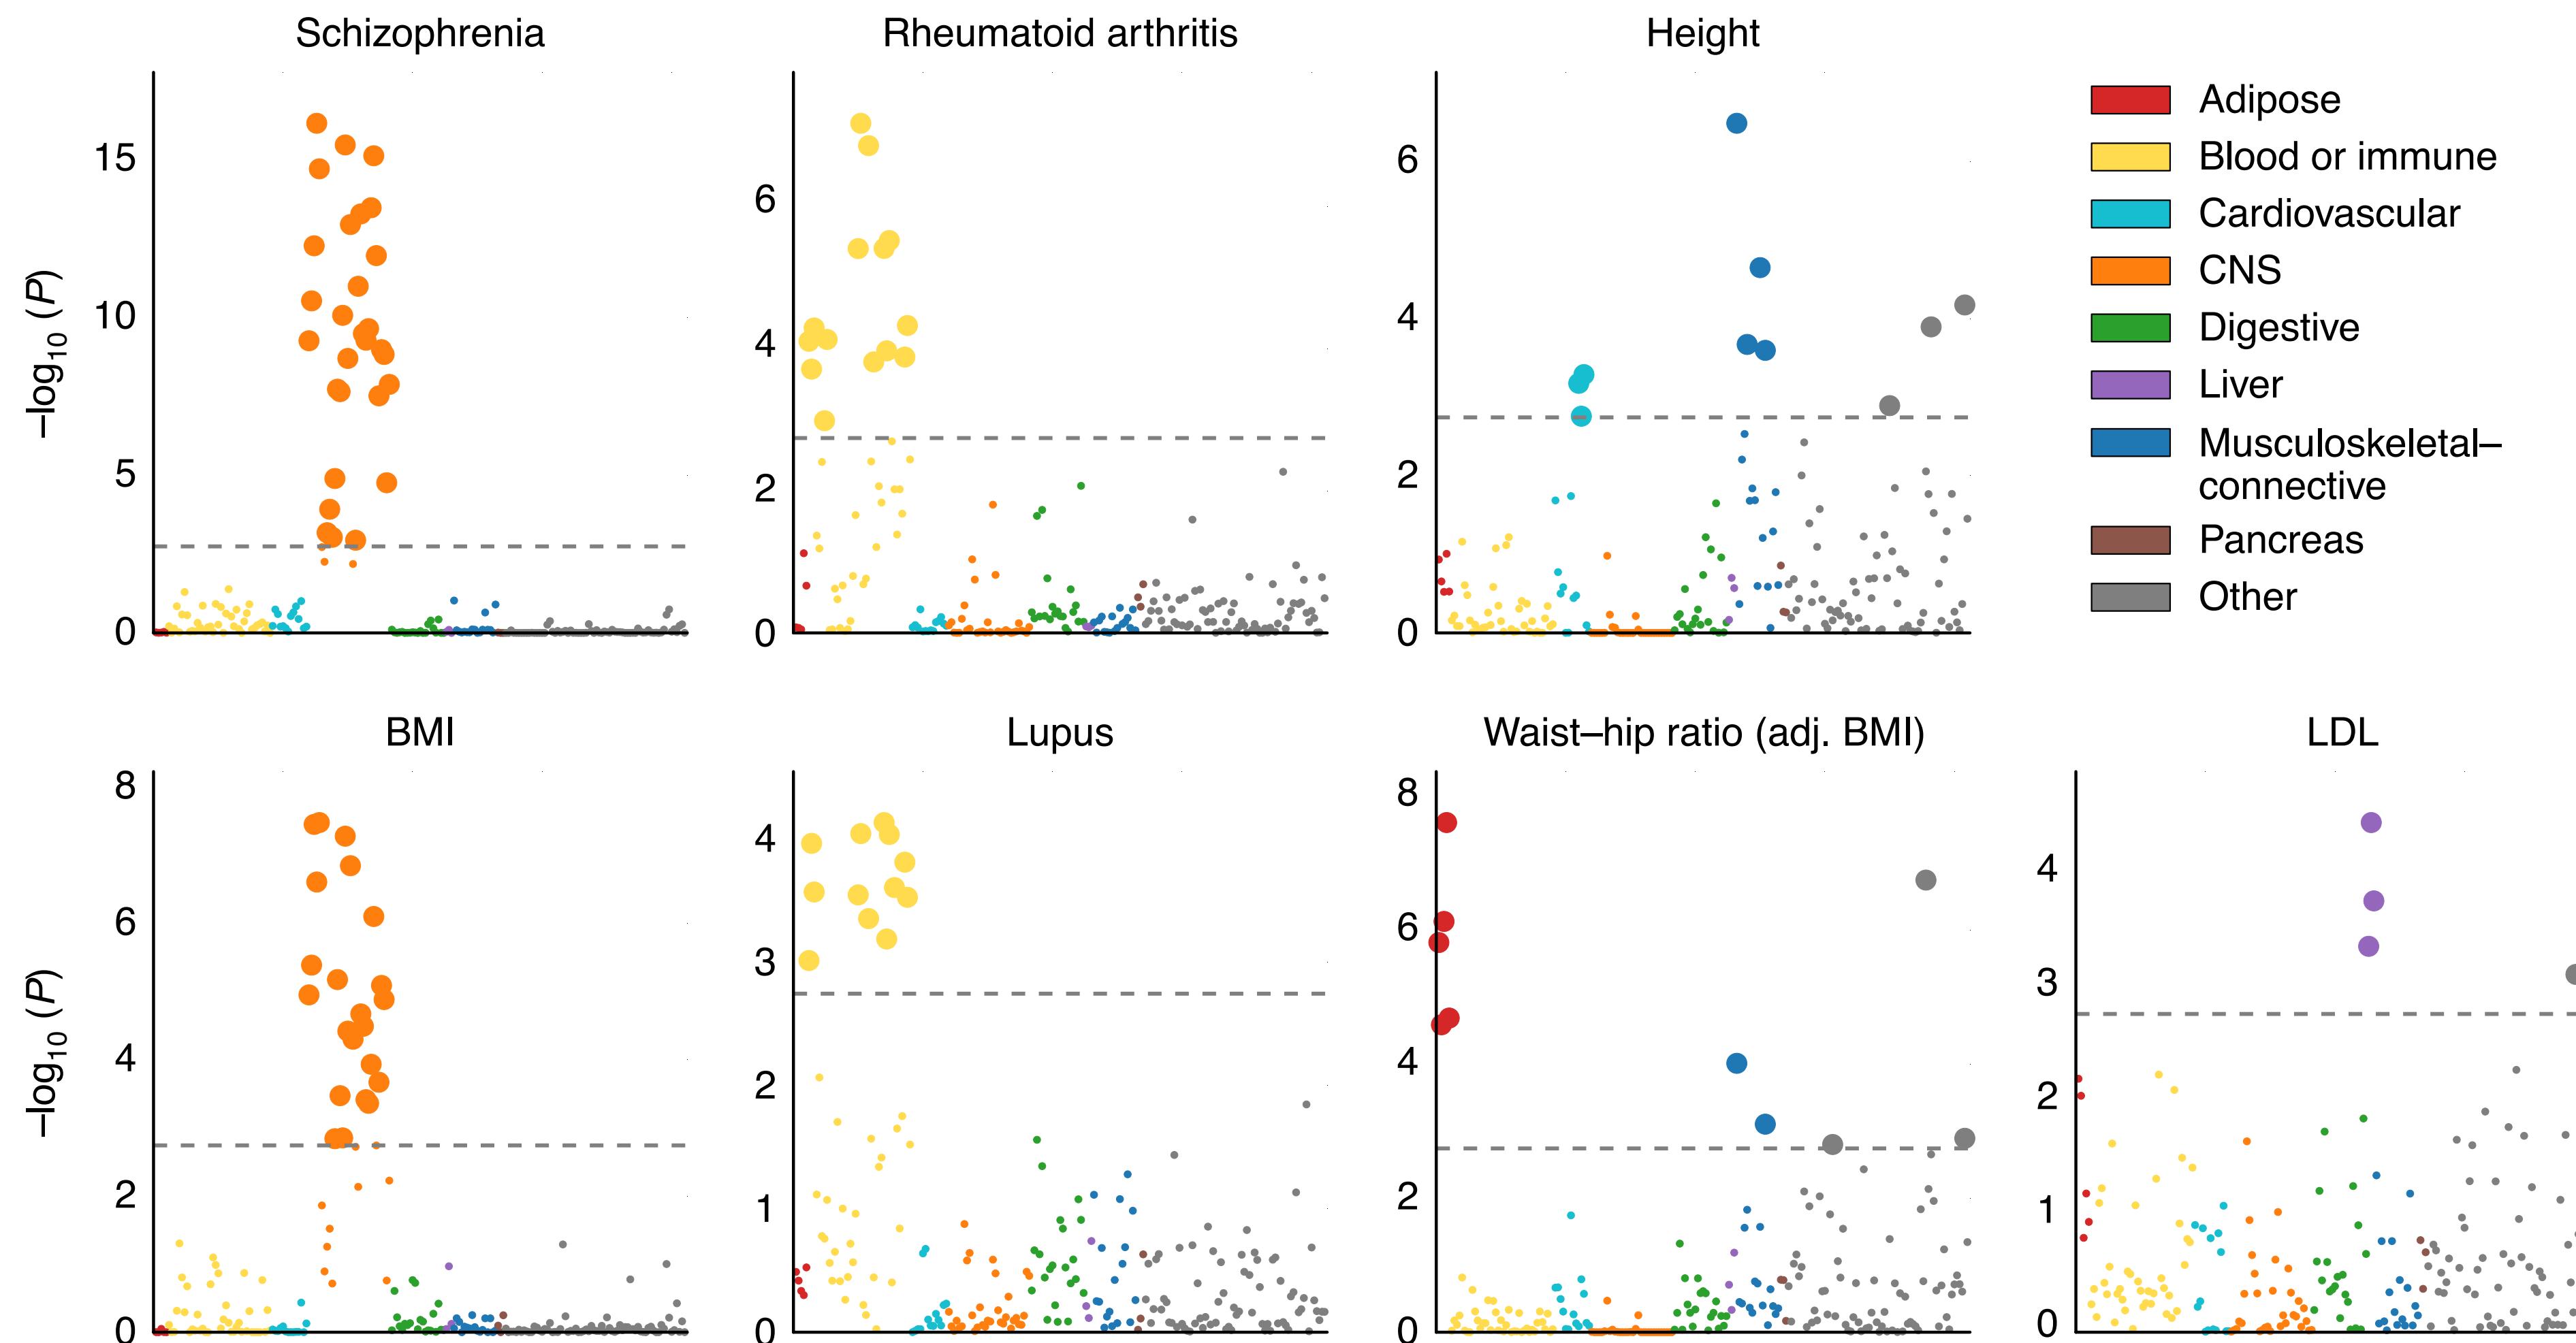

$$l_{jt} = \sum_k R_{jk}^2 I\{k \in \mathcal{A}_t\}.$$

More explicitly,

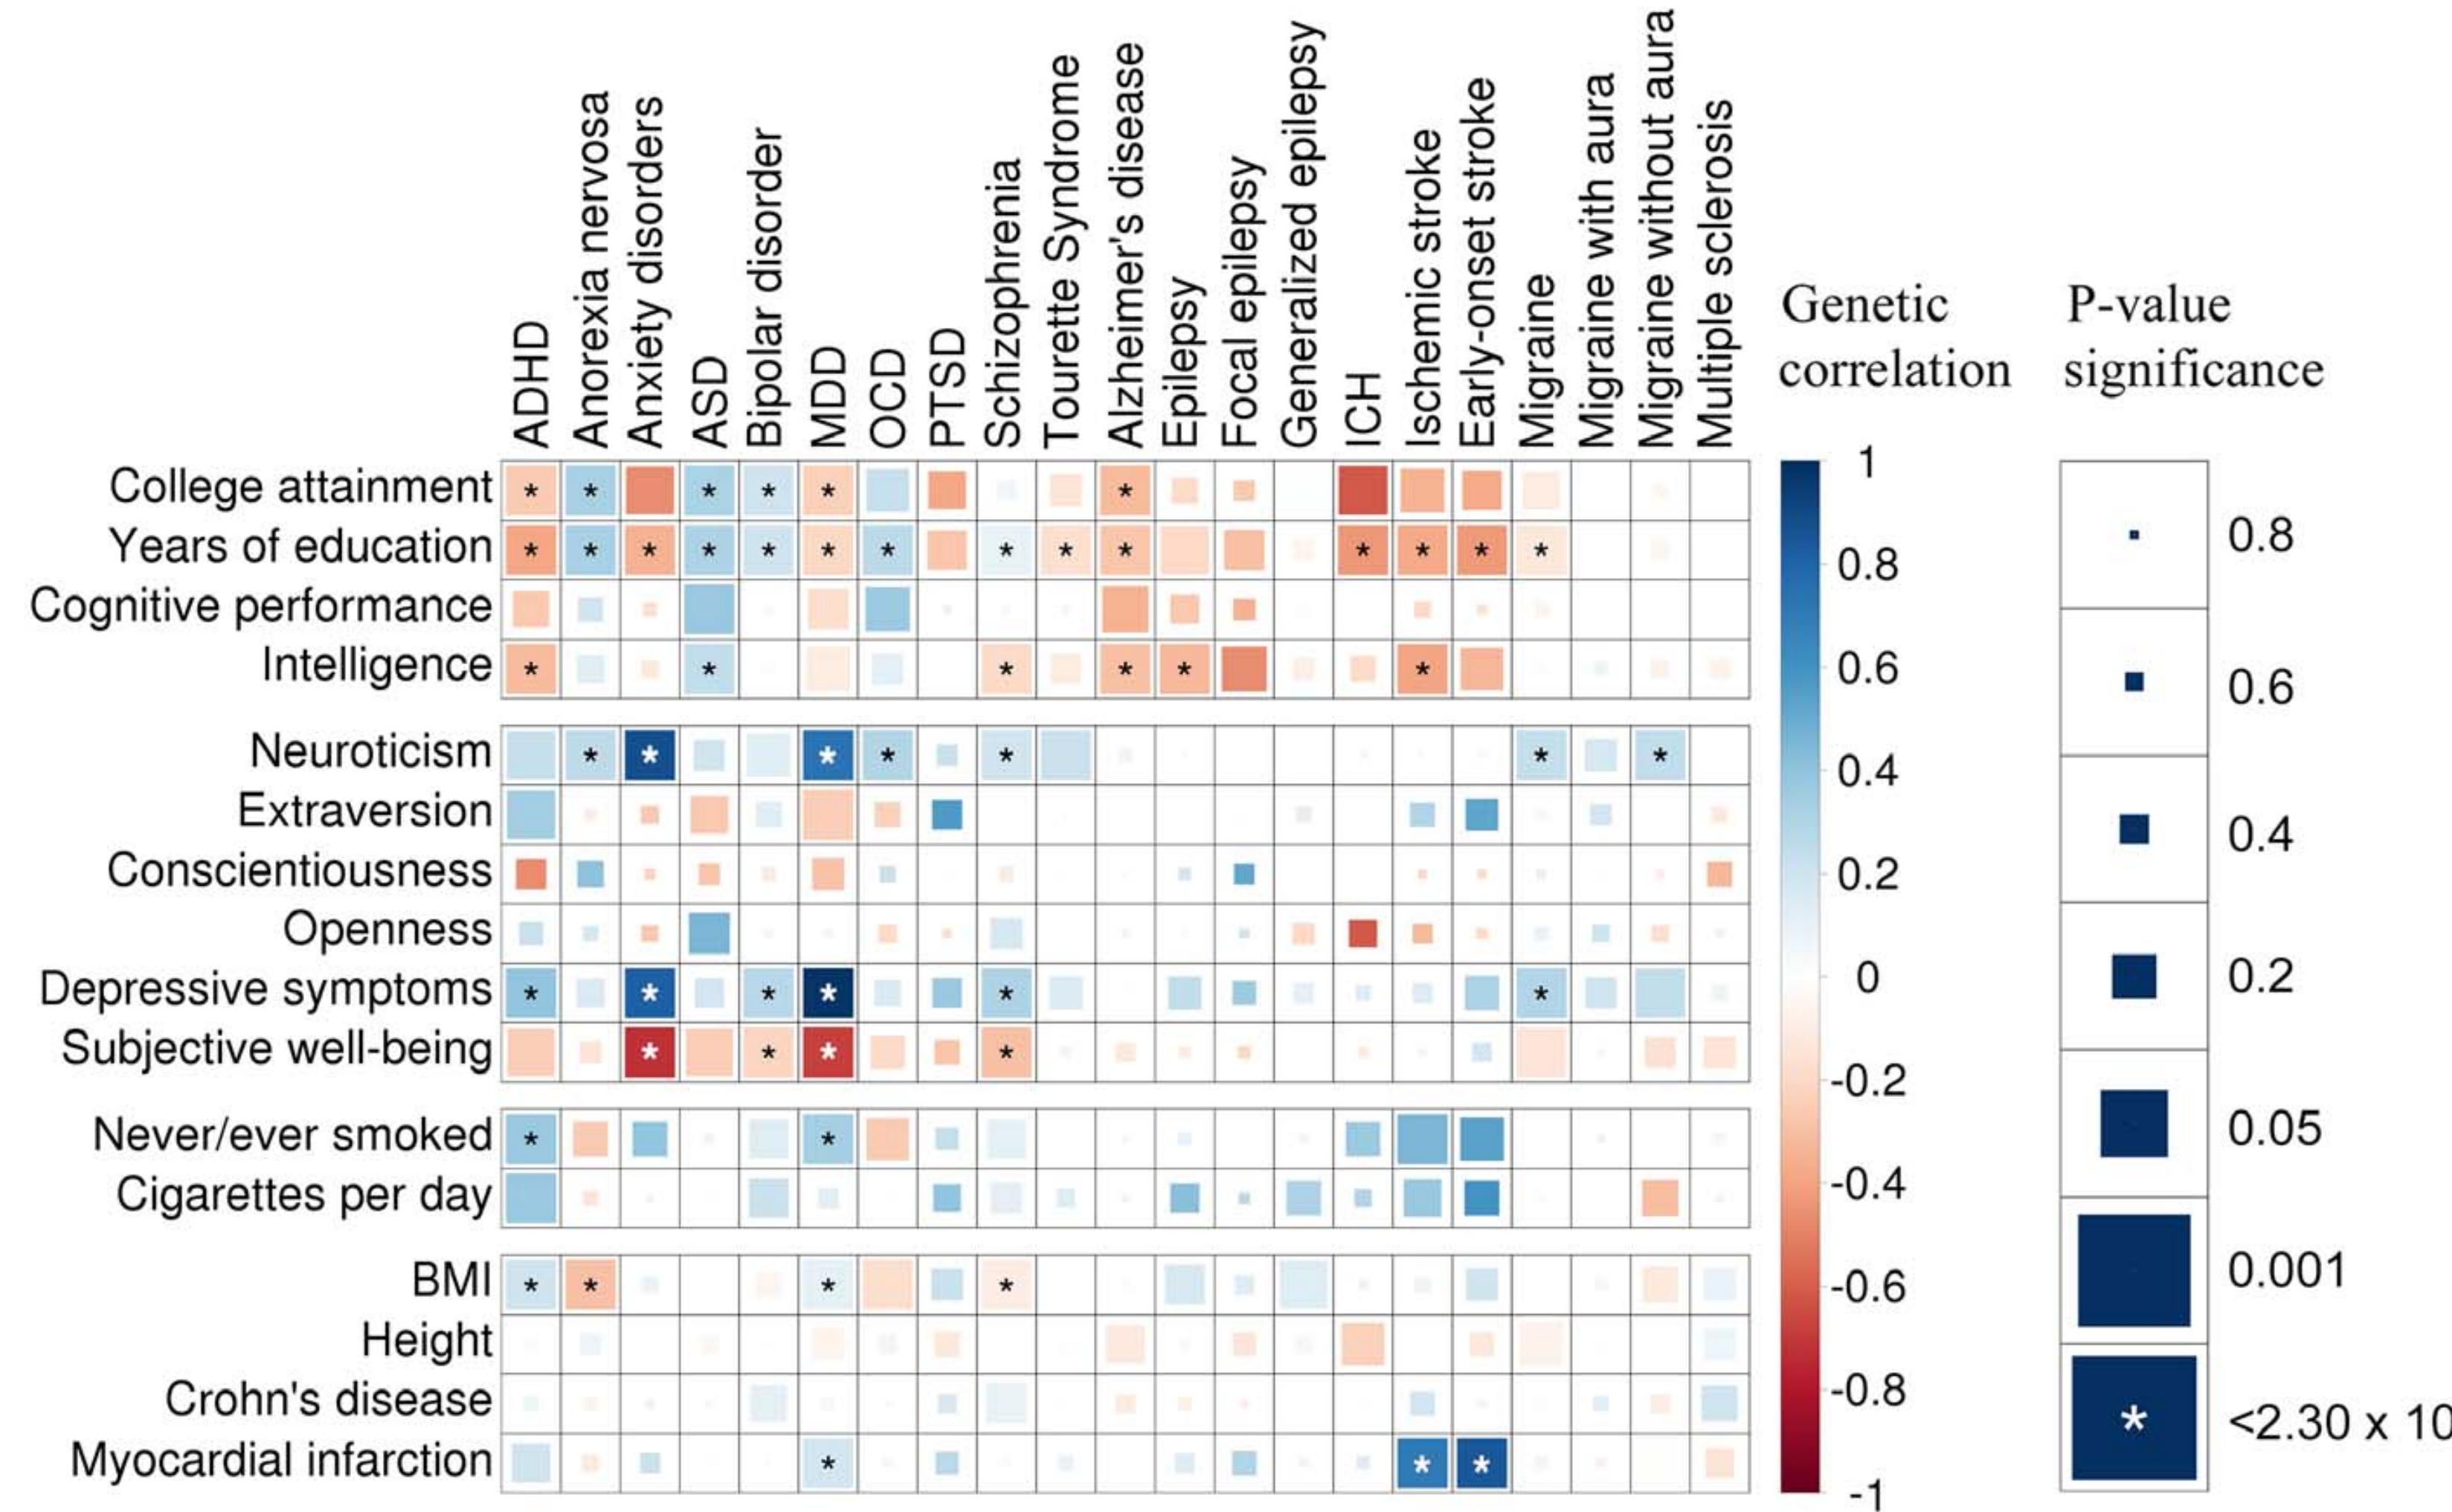

$$\begin{pmatrix} \chi_1^2 \\ \vdots \\ \chi_j^2 \\ \vdots \end{pmatrix} \sim \frac{n}{p} \begin{pmatrix} l_{11} & l_{12} & l_{1t} & \dots \\ \vdots & \vdots & \vdots & \vdots \\ l_{j1} & l_{j2} & l_{jt} & \dots \\ \vdots & \vdots & \vdots & \vdots \end{pmatrix} \begin{pmatrix} \tau_1 \\ \vdots \\ \tau_t \\ \vdots \end{pmatrix} + n\phi + 1$$

stratified LD scores stratified heritability genomic inflation null

Stratified LDSC can identify tissue-specific enrichment of GWAS signals

When multiple GWAS were done, post-GWAS analysis begins

Bivariate LD-score regression

Instead of one χ^2 vector, we need to deal with the element-wise product of two vectors of z-scores (between a trait 1 and 2):

$$\begin{pmatrix} z_1^{(1)} z_1^{(2)} l_1 \\ \vdots \\ z_j^{(1)} z_j^{(2)} l_j \\ \vdots \end{pmatrix} \sim \frac{\sqrt{N_1 N_2}}{p} \begin{pmatrix} l_1 \\ \vdots \\ l_j \\ \vdots \end{pmatrix} + \frac{\rho_0 N_s}{\sqrt{N_1 N_2}}$$

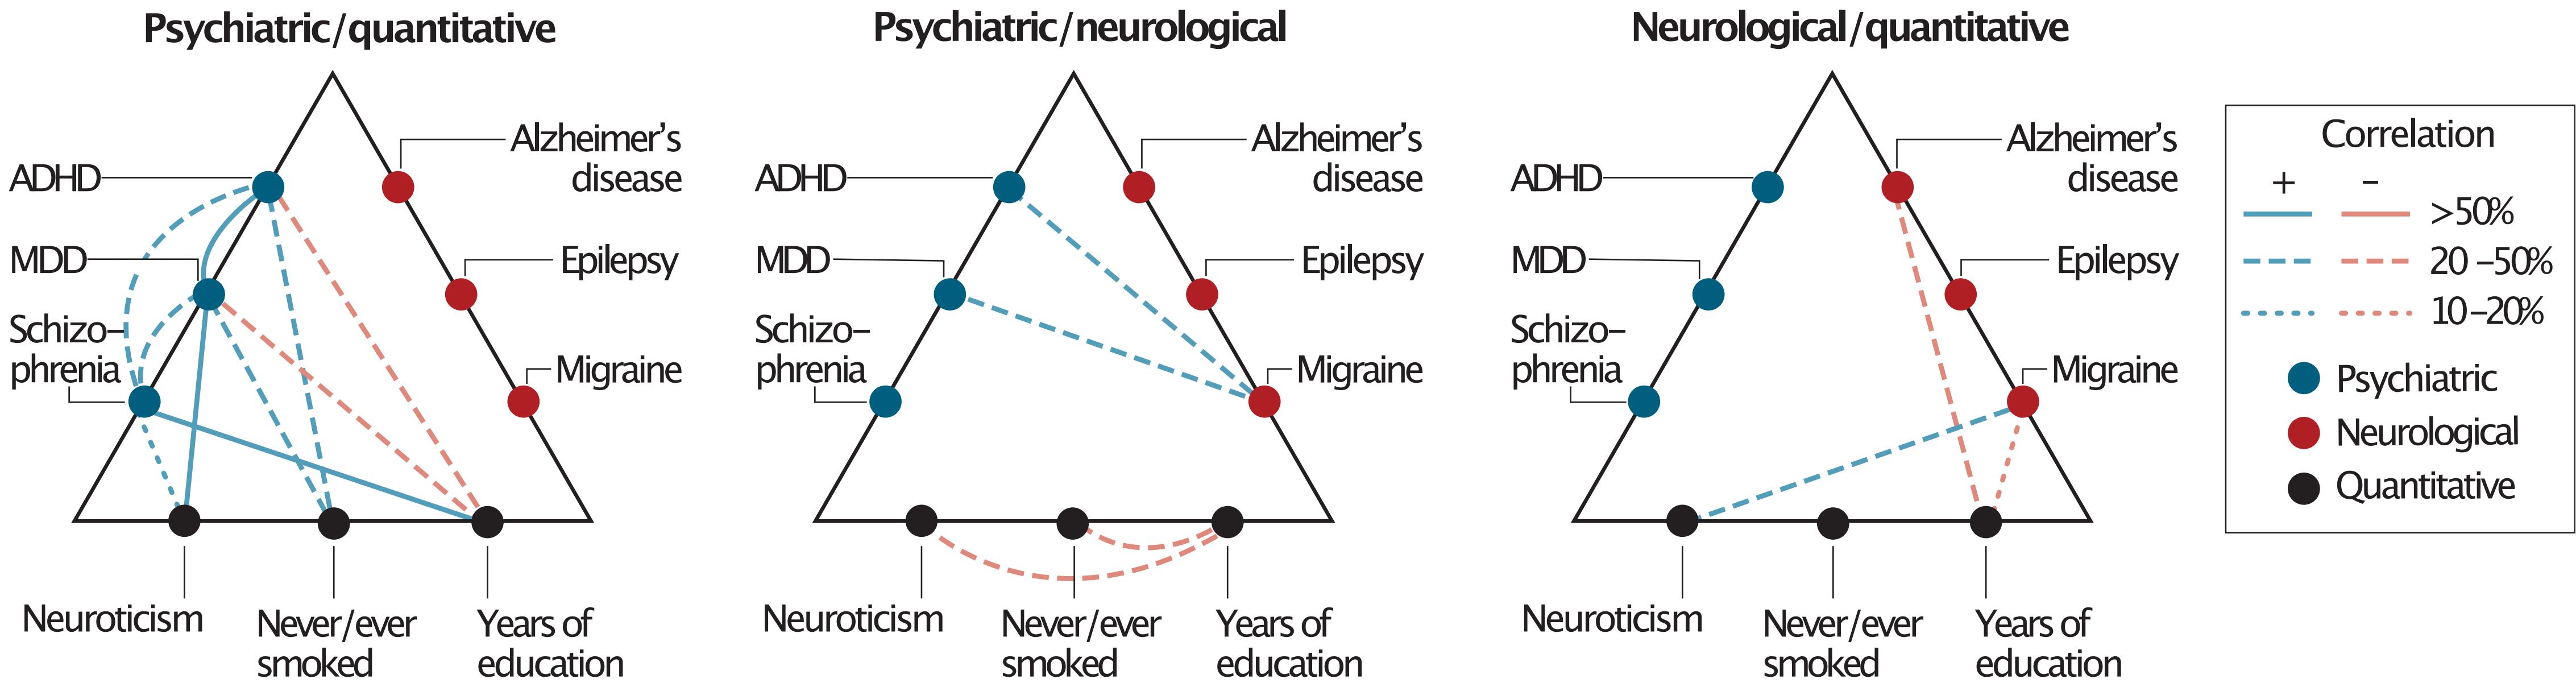

genetic correlation sample sharing

where N_1 and N_2 count sample size of the GWAS 1 and 2; N_s is the number of control individuals shared between the two traits.

Post-GWAS analysis example: genetic correlations across many traits
